HYDRODYNAMICS.

History.
Definition.

1. HYDRODYNAMICS, from ὑδωρ, "water," and δυναμις, "power," is properly that science which treats of the power of water, whether it acts by pressure or by impulse. In its more enlarged acceptation, however, it treats of the pressure, equilibrium, cohesion, and motion of fluids, and of the machines by which water is raised, or in which that fluid is employed as the first mover. Hydrodynamics is divided into two branches, *Hydrostatics* and *Hydraulics*. Hydrostatics comprehends the pressure, equilibrium, and cohesion of fluids, and Hydraulics their motion, together with the machines in which they are chiefly concerned.

HISTORY.

Hydrodynamics in some respects a modern science.

2. The science of hydrodynamics was cultivated with less success among the ancients than any other branch of mechanical philosophy. When the human mind had made considerable progress in the other departments of physical science, the doctrine of fluids had not begun to occupy the attention of philosophers; and, if we except a few propositions on the pressure and equilibrium of water, hydrodynamics must be regarded as a modern science, which owes its existence and improvement to those great men who adorned the seventeenth and eighteenth centuries.

Discoveries of Archimedes. A. C. 250.

3. Those general principles of hydrostatics which are to this day employed as the foundation of that part of the science, were first given by Archimedes in his work Περι ὀχουμενων, or *De Insidentibus Humido*, about 250 years before the birth of Christ, and were afterwards applied to experiments by Marinus Ghetaldus in his *Archimedes Promotus*. Archimedes maintained that each particle of a fluid mass, when in equilibrio, is equally pressed in every direction; and he inquired into the conditions, according to which a solid body floating in a fluid should assume and preserve a position of equilibrium. We are also indebted to the philosopher of Syracuse for that ingenious hydrostatic process by which the purity of the precious metals can be ascertained, and for the screw engine which goes by his name, the theory of which has lately exercised the ingenuity of some of our greatest mathematicians.

History.

Inventions of Ctesibius and Hero. A. D. 120.

4. In the Greek school at Alexandria which flourished under the auspices of the Ptolemies, the first attempts were made at the construction of hydraulic machinery. About 120 years after the birth of Christ, the fountain of compression, the syphon, and the forcing pump, were invented by Ctesibius and Hero; and though these machines operated by the elasticity and weight of the air, yet their inventors had no distinct notions of these preliminary branches of pneumatical science. The syphon is a simple instrument which is employed to empty vessels full of water or spirituous liquors, and is of great utility in the arts. The forcing pump, on the contrary, is a complicated and abstruse invention, which could scarcely have been expected in the infancy of hydraulics. It was probably suggested to Ctesibius by the *Egyptian wheel* or *Noria*, which was common at that time, and which was a kind of chain pump, consisting of a number of earthern pots carried round by a wheel. In some of these machines the pots have a valve in their bottom which enables them to descend without much resistance, and diminishes greatly the load upon the wheel; and if we suppose that this valve was introduced so early as the time of Ctesibius, it is not difficult to perceive how such a machine might have led this philosopher to the invention of the forcing pump.

Forcing Pump.

Egyptian wheel.

Labours of Sextus Julius Frontinus in hydraulics. A. D. 110.

5. Notwithstanding these inventions of the Alexandrian school, its attention does not seem to have been directed to the motion of fluids. The first attempt to investigate this subject was made by Sextus Julius Frontinus, inspector of the public fountains at Rome in the reigns of Nerva and Trajan; and we may justly suppose that his work entitled *De Aquæductibus urbis Romæ Commentarius* contains all the hydraulic knowledge of the ancients. After

History. describing the *nine*[1] great Roman aqueducts, to which he himself added *five* more, and mentioning the dates of their erection, he considers the methods which were at that time employed for ascertaining the quantity of water discharged from adjutages, and the mode of distributing the waters of an aqueduct or a fountain. He justly remarks that the expense of water from an orifice, depended not only on the magnitude of the orifice itself, but also on the height of the water in the reservoir; and that a pipe employed to carry off a portion of water from an aqueduct, should, as circumstances required, have a position more or less inclined to the original direction of the current. But as he was unacquainted with the true law of the velocities of running water as depending upon the depth of the orifice, we can scarcely be surprised at the want of precision which appears in his results.

The Romans acquainted with the art of conducting water in pipes.

It has generally been supposed that the Romans were ignorant of the art of conducting and raising water by means of pipes; but it can scarcely be doubted, from the statement of Pliny and other authors, that they not only were acquainted with the hydrostatical principle, but that they actually used leaden pipes for the purpose. Pliny asserts that water will always rise to the height of its source, and he also adds that, in order to raise water up to an eminence, leaden pipes must be employed.[2]

6. The labours of the ancients in the science of hydrodynamics terminated with the life of Frontinus. The sciences had already begun to decline, and that night of ignorance and barbarism was advancing apace, which for more than a thousand years brooded over the nations of Europe. During this lengthened period of mental degeneracy, when less abstruse studies ceased to attract the notice, and rouse the energies of men, the human mind could not be supposed capable of that vigorous exertion, and patient industry, which are so indispensable in physical researches. Poetry and the fine arts, accordingly, had made considerable progress under the patronage of the family of Medici, before Galileo began to extend the boundaries of science. This great man, who deserves to be called the father and restorer of physics, does not appear to have directed his attention to the doctrine of fluids: but his discovery of the uniform acceleration of gravity, laid the foundation of its future progress, and contributed in no small degree to aid the exertions of genius in several branches of science.

Labours of Galileo. Born 1564, died 1641.

Of Castelli. Born 1577, died 1644.

7. Castelli and Torricelli, two of the disciples of Galileo, applied the discoveries of their master to the science of hydrodynamics. In 1628 Castelli published a small work, *Della Misura dell 'acque correnti*, in which he gave a very satisfactory explanation of several phenomena in the motion of fluids, in rivers and canals. But he committed a great paralogism in supposing the velocity of the water proportional to the depth of the orifice below the surface of the vessel. Torricelli observing that in a *jet d'eau* where the water rushed through a small adjutage, it rose to nearly the same height with the reservoir from which it was supplied, imagined that it ought to move with the same velocity as if it had fallen through that height by the force of gravity. And hence he deduced this beautiful and important proposition, that the velocities of fluids are as the square roots of the pressures, abstracting from the resistance of the air and the friction of the orifice. This theorem was published in 1643, at the end of his treatise *De Motu Gravium naturaliter accelerato*. It was afterwards confirmed by the experiments of Raphael Magiotti, on the quantities of water discharged from different adjutages under different pressures; and though it is true only in small orifices, it gave a new turn to the science of hydraulics.

Of Torricelli. Born 1608, died 1647.

History.

Of Pascal. Born 1623, died 1662.

8. After the death of the celebrated Pascal, who discovered the pressure of the atmosphere, a treatise on the equilibrium of fluids (*Sur l'Equilibre des Liqueurs*), was found among his manuscripts, and was given to the public in 1663. In the hands of Pascal, hydrostatics assumed the dignity of a science. The laws of the equilibrium of fluids were demonstrated in the most perspicuous and simple manner, and amply confirmed by experiments. The discovery of Torricelli, it may be supposed, would have incited Pascal to the study of hydraulics. But as he has not treated this subject in the work which has been mentioned, it was probably composed before that discovery had been made public.

Of Mariotte. Died 1684.

9. The theorem of Torricelli was employed by many succeeding writers, but particularly by the celebrated Mariotte, whose labours in this department of physics deserve to be recorded. His *Traité du Mouvement des Eaux*, which was published after his death in the year 1686, is founded on a great variety of well-conducted experiments on the motion of fluids, performed at Versailles and Chantilly. In the discussion of some points he has committed considerable mistakes. Others he has treated very superficially, and in none of his experiments does he seem to have attended to the diminution of efflux arising from the contraction of the fluid vein, when the orifice is merely a perforation in a thin plate; but he appears to have been the first who attempted to ascribe the discrepancy between theory and experiment to the retardation of the water's velocity arising from friction. His cotemporary Guglielmini, who was inspector of the rivers and canals in the Milanese, had ascribed this diminution of velocity in rivers, to transverse motions arising from inequalities in their bottom. But as Mariotte observed similar obstructions even in glass pipes, where no transverse currents could exist, the cause assigned by Guglielmini seemed destitute of foundation. The French philosopher, therefore, regarded these obstructions as the effects of friction. He supposes that the filaments of water which graze along the sides of the pipe lose a portion of their velocity; that the contiguous filaments having on this account a greater velocity, rub upon the former, and suffer a diminution of their celerity; and that the other filaments are affected with similar retardations proportional to their distance from the axis of the pipe. In this way the medium velocity of the current may be diminished, and consequently the quantity of water discharged in a given time, must, from the effects of friction, be considerably less than that which is computed from theory.

The motion of rivers first attended to in Italy.

10. That part of the science of hydrodynamics which relates to the motion of rivers seems to have originated in Italy. This fertile country receives from the Apennines a great number of torrents, which traverse several principalities before they mingle their waters with those of the Po, into which the greater part of them fall. To defend themselves from the inundations with which they were threatened, it became necessary for the inhabitants to change the course of their rivers; and while they thus drove them from their own territories, they let them loose on those of their neighbours. Hence arose the continual quarrels which once raged between the Bolognese and the inhabitants of Modena and Ferrara. The attention of the Italian engineers was necessarily directed to this branch of science; and from this cause a greater number of works

---

[1] These nine aqueducts delivered every day 14,000 quinaria, or about 50,000,000 cubic feet of water, or about 50 cubic feet for the daily consumption of each inhabitant, supposing the population of Rome to have been a million. According to Professor Leslie, the supply in modern Rome is forty cubic feet per person, in London three cubic feet, and in Paris one-half a cubic foot.—See *Elements of Nat. Phil.* p. 419.

History.

were written on the subject in Italy than in all the rest of Europe.

Theory of Guglielmini.

11. Guglielmini was the first who attended to the motion of water in rivers and open canals.[1] Embracing the theorem of Torricelli, which had been confirmed by repeated experiments, Guglielmini concluded that each particle in the perpendicular section of a current has a tendency to move with the same velocity as if it issued from an orifice at the same depth from the surface. The consequences deducible from this theory of running waters are in every respect repugnant to experience, and it is really surprising that it should have been so hastily adopted by succeeding writers. Guglielmini himself was sufficiently sensible that his parabolic theory was contrary to fact, and endeavoured to reconcile them by supposing the motion of rivers to be obstructed by transverse currents arising from irregularities in their bed. The solution of this difficulty, as given by Mariotte, was more satisfactory, and was afterwards adopted by Guglielmini, who maintained also that the viscidity of water had a considerable share in retarding its motion.

Discoveries of Sir Isaac Newton. Born 1652, died 1727

12. The effects of friction and viscidity in diminishing the velocity of running water were noticed in the *Principia* of Sir Isaac Newton, who has thrown much light upon several branches of hydrodynamics. At a time when the Cartesian system of vortices universally prevailed, this great man found it necessary to investigate that absurd hypothesis, and in the course of his investigations he has shewn that the velocity of any stratum of the vortex is an arithmetical mean between the velocities of the strata which enclosed it; and from this it evidently follows, that the velocity of a filament of water moving in a pipe is an arithmetical mean between the velocities of the filaments which surround it. Taking advantage of these results, it was afterwards shewn by M. Pitot, that the retardations arising from friction are inversely as the diameters of the pipes in which the fluid moves. The attention of Newton was also directed to the discharge of water from orifices in the bottom of vessels. He supposed a cylindrical vessel full of water to be perforated in its bottom with a small hole by which the water escaped, and the vessel to be supplied with water in such a manner that it always remained full at the same height. He then supposed this cylindrical column of water to be divided into two parts; the first, which he calls the *cataract*, being a hyperboloid generated by the revolution of a hyperbola of the fifth degree around the axis of the cylinder which should pass through the orifice; and the second the remainder of the water in the cylindrical vessel. He considered the horizontal strata of this hyperboloid as always in motion, while the remainder of the water was in a state of rest; and imagined that there was a kind of cataract in the middle of the fluid. When the results of this theory were compared with the quantity of water actually discharged, Newton concluded that the velocity with which the water issued from the orifice was equal to that which a falling body would receive by descending through half the height of water in the reservoir. This conclusion, however, is absolutely irreconcilable with the known fact, that jets of water rise nearly to the same height as their reservoirs, and Newton seems to have been aware of this objection. In the second edition of his *Principia*, accordingly, which appeared in 1714, Sir Isaac has reconsidered his theory. He had discovered a contraction in the vein of fluid (*vena contracta*), which issued from the orifice, and found that, at the distance of about a diameter of the aperture, the section of the vein was contracted in the subduplicate ratio of two to one. He regarded, therefore, the section of the contracted vein as the true orifice from which the discharge of water ought to be deduced, and the velocity of the effluent water as due to the whole height of water in the reservoir; and by this means his theory became more conformable to the results of experience. This theory, however, is still liable to serious objections. The formation of a *cataract* is by no means agreeable to the laws of hydrostatics; for when a vessel is emptied by the efflux of water through an orifice in its bottom, all the particles of the fluid direct themselves toward this orifice, and therefore no part of it can be considered as in a state of repose.

History.

The oscillation of waves first considered by Newton.

13. The subject of the oscillation of waves, one of the most difficult in the science of hydrodynamics, was first investigated by Sir Isaac Newton. In the forty-fourth proposition of the second book of his *Principia*, he has furnished us with a method of ascertaining the velocity of the waves of the sea, by observing the time in which they rise and fall. If the two vertical branches of a syphon, which communicate by means of a horizontal branch, be filled with a fluid of known density, the two fluid columns, when in a state of rest, will be in equilibrio and their surfaces horizontal. But if the one column is raised above the level of the other, and left to itself, it will descend below that level, and raise the other column above it, and, after a few oscillations, they will return to a state of repose. Newton occupied himself in determining the duration of these oscillations, or the length of a pendulum isochronous to their duration; and he found, by a simple process of reasoning, that, abstracting from the effects of friction, the length of a synchronous pendulum is equal to one-half of the length of the syphon, that is, of the two vertical branches and the horizontal one, and hence he deduced the isochronism of these oscillations. From this Newton concluded, that the velocity of waves formed on the surface of water, either by the wind or by means of a stone, was in the subduplicate ratio of their size. When their velocity, therefore, is measured, which can be easily done, the size of the waves will be determined by taking a pendulum which oscillates in the time that a wave takes to rise and fall.

Labours of the Marquis Poleni. Born 1683, died 1761.

14. In the year 1718, the Marquis Poleni published, at Padua, his work *De Castellis per quæ derivantur Fluviorum aquæ*, &c. He found, from a great number of experiments, that if A be the aperture of the orifice, and D its depth below the surface of the reservoir, the quantity of water discharged in a given time will be as $2\,AD \times \frac{0.571}{1.000}$, while it ought to be as $2\,AD$, if the velocity of the issuing fluid was equal to that acquired by falling through D. By adapting to a circular orifice through which the water escaped, a cylindrical tube of the same diameter, the Marquis found that the quantity discharged in a determinate time was considerably greater than when it issued from the circular orifice itself; and this happened whether the water descended perpendicularly or issued in a horizontal direction.

Daniel Bernouilli's theory of the motion of fluids. Born 1700. Died 1782.

15. Such was the state of hydrodynamics in 1738, when Daniel Bernouilli published his *Hydrodynamica, seu de viribus et motibus Fluidorum Commentarii*. His theory of the motion of fluids was founded on two suppositions, which appeared to him conformable to experience. He supposed that the surface of a fluid, contained in a vessel which was emptying itself by an orifice, remains always horizontal; and if the fluid mass is conceived to be divided into an infinite number of horizontal strata of the same bulk, that these strata remain contiguous to each other, and that all their points descend vertically, with velocities inversely proportional to their breadth, or to the horizontal sections of the reservoir. In order to determine the motion of each stratum, he employed the principle of the *conservatio viri-*

[1] See his principal work, entitled *La Misura dell' acque correnti.*

History. *um vivarum*, and obtained very elegant solutions. In the opinion of the Abbé Bossut, his work was one of the finest productions of mathematical genius.[1]

Objected to by Maclaurin, Born 1698, died 1746; and John Bernouilli, Born 1667, died 1748.

16. The uncertainty of the principle employed by Daniel Bernouilli, which has never been demonstrated in a general manner, deprived his results of that confidence which they would otherwise have deserved; and rendered it desirable to have a theory more certain, and depending solely on the fundamental laws of mechanics. Maclaurin and John Bernouilli, who were of this opinion, resolved the problem by more direct methods, the one in his Fluxions, published in 1742; and the other in his *Hydraulica nunc primum detecta, et directe demonstrata ex principiis purè mechanicis*, which forms the fourth volume of his works. The method employed by Maclaurin has been thought not sufficiently rigorous; and that of John Bernouilli is, in the opinion of La Grange, defective in perspicuity and precision.

D'Alembert applies his principle of dynamics to the motion of fluids, Born 1717.

17. The theory of Daniel Bernouilli was opposed also by the celebrated D'Alembert. When generalising James Bernouilli's Theory of Pendulums, he discovered a principle of dynamics so simple and general, that it reduced the laws of the motions of bodies to that of their equilibrium. He applied this principle to the motion of fluids, and gave a specimen of its application at the end of his Dynamics in 1743. It was more fully developed in his *Traité des Fluides*, which was published in 1744, where he has resolved, in the most simple and elegant manner, all the problems which relate to the equilibrium and motion of fluids. He makes use of the very same suppositions as Daniel Bernouilli, though his calculus is established in a very different manner. He considers, at every instant, the actual motion of a stratum, as composed of a motion which it had in the preceding instant, and of a motion which it has lost. The laws of equilibrium between the motions lost, furnish him with equations which represent the motion of the fluid. Although the science of hydrodynamics had then made considerable progress, yet it was chiefly founded on hypothesis. It remained a desideratum to express by equations the motion of a particle of the fluid in any assigned direction. These equations were found by D'Alembert, from two principles, that a rectangular canal, taken in a mass of fluid in equilibrio, is itself in equilibrio; and that a portion of the fluid, in passing from one place to another, preserves the same volume when the fluid is incompressible, or dilates itself according to a given law when the fluid is elastic. His very ingenious method was published in 1752, in his *Essai sur la resistanee des fluides*. It was brought to perfection in his *Opuscules Mathématiques*, and has been adopted by the celebrated Euler.

Before the time of D'Alembert, it was the great object of philosophers to submit the motion of fluids to general formulæ, independent of all hypothesis. Their attempts, however, were altogether fruitless; for the method of fluxions, which produced such important changes in the physical sciences, was but a feeble auxiliary in the science of hydraulics. For the resolution of the questions concerning the motion of fluids, we are indebted to the method of partial differences, a new calculus, with which Euler enriched the sciences. This great discovery was first applied to the motion of water by the celebrated D'Alembert, and enabled both him and Euler to represent the theory of fluids in formulæ restricted by no particular hypothesis.

Experiments of Michelotti, A. D. 1764.

18. An immense number of experiments on the motion of water in pipes and canals was made by Professor Michelotti of Turin, at the expense of the sovereign. In these experiments the water issued from holes of different sizes, under pressures of from 5 to 22 feet, from a tower constructed of the finest masonry. Basins (one of which was 289 feet square) built of masonry, and lined with stucco, received the effluent water, which was conveyed in canals of brickwork, lined with stucco, of various forms and declivities. The whole of Michelotti's experiments were conducted with the utmost accuracy; and his results, which are in every respect entitled to our confidence, were published in 1774 in his *Sperienze Idrauliche*.

Of the Abbe Bossut.

19. The experiments of the Abbé Bossut, whose labours in this department of science have been very assiduous and successful, have, in as far as they coincide, afforded the same results as those of Michelotti. Though performed on a smaller scale, they are equally entitled to our confidence, and have the merit of being made in cases which are most likely to occur in practice. In order to determine what were the motions of the fluid particles in the interior of a vessel emptying itself by an orifice, M. Bossut employed a glass cylinder, to the bottom of which different adjutages were fitted; and he found that all the particles descend at first vertically, but that at a certain distance from the orifice they turn from their first direction towards the aperture. In consequence of these oblique motions, the fluid vein forms a kind of truncated conoid, whose greatest base is the orifice itself, having its altitude equal to the radius of the orifice, and its bases in the ratio of 3 to 2.—It appears also, from the experiments of Bossut, that when water issues through an orifice made in a thin plate, the expense of water, as deduced from theory, is to the real expense as 16 to 10, or as 8 to 5; and, when the fluid issues through an additional tube, two or three inches long, and follows the sides of the tube, as 16 to 13.—In analyzing the effects of friction, he found, 1. That small orifices gave less water in proportion than great ones, on account of friction; and, 2. That when the height of the reservoir was augmented, the contraction of the fluid vein was also increased, and the expense of water diminished; and by means of these two laws he was enabled to determine the quantity of water discharged, with all the precision he could wish. In his experiments on the motion of water in canals and tubes, he found that there was a sensible difference between the motion of water in the former and in the latter. Under the same height of reservoir, the same quantity of water always flows in a canal, whatever be its length and declivity; whereas, in a tube, a difference in length and declivity has a very considerable influence on the quantity of water discharged. According to the theory of the resistance of fluids, the impulse upon a plane surface is as the product of its area multiplied by the square of the fluid's velocity, and the square of the sine of the angle of incidence. The experiments of Bossut, made in conjunction with D'Alembert and Condorcet, prove, that this is sensibly true when the impulse is perpendicular; but that the aberrations from theory increase with the angle of impulsion. They found, that when the angle of impulsion was between 50° and 90°, the ordinary theory may be employed, that the resistances thus found will be a little less than they ought to be, and the more so as the angles recede from 90°. The attention of Bossut was directed to a variety of other interesting points, which we cannot stop to notice, but for which we must refer the reader to the works of that ingenious author.

Inquiries of Flaugergues concerning the oscillation of waves.

20. The oscillation of waves, which was first discussed by Sir Isaac Newton, and afterwards by D'Alembert, in the article *Ondes* in the French Encyclopædia, was now revived by M. Flaugergues, who attempted to overthrow the opinions of these philosophers. He maintained, that a wave is not the effect of a motion in the particles of water,

[1] The germ of Daniel Bernouilli's theory was first published in his memoir entitled *Theoria Nova de Motu Aquarum per Canales quocunque Fluentes*, which he had communicated to the Academy of St Petersburg as early as 1726.

History.

by which they rise and fall alternately, in a serpentine line, when moving from the centre where they commenced; but that it is a kind of intumescence, formed by a depression at the place where the impulse is first made, which propagates itself in a circular manner when removing from the point of impulse. A portion of the water, thus elevated, he imagines, flows from all sides into the hollow formed at the centre of impulse, so that the water being, as it were, heaped up, produces another intumescence, which propagates itself as formerly. From this theory M. Flaugergues concludes, and he has confirmed the conclusion by experiment, that all waves, whether great or small, have the same velocity.

And of M. de la Grange. Born 1730, died 1813.

21. This difficult subject has also been discussed by M. de la Grange, in his *Mécanique Analytique*. He found, that the velocity of waves, in a canal, is equal to that which a heavy body would acquire by falling through a height equal to half the depth of the water in the canal. If this depth, therefore, be one foot, the velocity of the waves will be 5.945 feet in a second; and if the depth is greater or less than this, their velocity will vary in the subduplicate ratio of the depth, provided it is not very considerable. If we suppose that, in the formation of waves, the water is agitated but to a very small depth, the theory of La Grange may be employed, whatever be the depth of the water and the figure of its bottom. This supposition, which is very plausible, when we consider the tenacity and adhesion of the particles of water, has also been confirmed by experience.

Experiments and theory of the Chevalier de Buat. A.D. 1779.

22. The most successful labourer in the science of hydrodynamics was the Chevalier Buat, engineer in ordinary to the King of France. Following in the steps of the Abbé Bossut, he prosecuted the inquiries of that philosopher with uncommon ingenuity; and in the year 1786, he published, in two volumes, his *Principes d'Hydraulique*,[1] which contains a satisfactory theory of the motion of fluids, founded solely upon experiments. The Chevalier du Buat considered, that if water were a perfect fluid, and the channels in which it flowed infinitely smooth, its motion would be continually accelerated, like that of bodies descending in an inclined plane. But as the motion of rivers is not continually accelerated, and soon arrives at a state of uniformity, it is evident that the viscidity of the water, and the friction of the channel in which it descends, must equal the accelerating force. M. Buat, therefore, assumes it as a proposition of fundamental importance, that when water flows in any channel or bed, the accelerating force, which obliges it to move, is equal to the sum of all the resistances which it meets with, whether they arise from its own viscidity or from the friction of its bed. This principle was employed by M. Buat, in the first edition of his work, which appeared in 1779; but the theory contained in that edition was founded on the experiments of others. He soon saw, however, that a theory so new, and leading to results so different from the ordinary theory, should be founded on new experiments more direct than the former, and he was employed in the performance of these from 1780 to 1783. The experiments of Bossut having been made only on pipes of a moderate declivity, M. Buat found it necessary to supply this defect. He used declivities of every kind, from the smallest to the greatest; and made his experiments upon channels, from a line and a half in diameter, to seven or eight square toises. All these experiments he arranged under some circumstances of resemblance, and produced the following proposition, which agrees in a most wonderful manner with the immense number of facts which he has brought together, viz.

$$V = \frac{307 \times \sqrt{d - 01}}{\sqrt{s} - L\sqrt{s + 1.6}} - 0.3 \times \overline{d - 0.1},$$

where d is the hydraulic mean depth, s the slope of the pipe, or of the surface of the current, and V the velocity with which the water issues.

Researches of M. Venturi. A.D. 1798.

23. M. Venturi, Professor of Natural Philosophy in the University of Modena, succeeded in bringing to light some curious facts respecting the motion of water, in his work on the "Lateral Communication of Motion in Fluids." He observed, that if a current of water is introduced with a certain velocity into a vessel filled with the same fluid at rest, and if this current passing through a portion of the fluid is received in a curvilineal channel, the bottom of which gradually rises till it passes over the rim of the vessel itself, it will carry along with it the fluid contained in the vessel; so that after a short time has elapsed, there remains only the portion of the fluid which was originally below the aperture at which the current entered. This phenomenon has been called by Venturi, the lateral communication of motion in fluids; and, by its assistance, he has explained many important facts in hydraulics. He has not attempted to explain this principle; but has shewn, that the mutual action of the fluid particles does not afford a satisfactory explanation of it. The work of Venturi contains many other interesting discussions, which are worthy of the attention of every reader.

Discoveries of Coulomb, A.D. 1800.

24. Although the Chevalier Buat had shown much sagacity in classifying the different kinds of resistances which are exhibited in the motion of fluids, yet it was reserved for Coulomb to express the sum of them by a rational function of the velocity. By a series of interesting experiments on the successive diminution of the oscillation of discs, arising from the resistance of the water in which they oscillated, he was led to the conclusion, that the pressure sustained by the moving disc is represented by two terms, one of which varies with the simple velocity, and the other with its square. When the motions are very slow, the part of the resistance proportional to the square of the velocity is insensible, and hence the resistance is proportional to the simple velocity. M. Coulomb found also, that the resistance is not perceptibly increased by increasing the depth of the oscillating disc in the fluid; and by coating the disc successively with fine and coarse sand, he found that the resistance arises solely from the mutual cohesion of the fluid particles, and from their adhering to the surface of the moving body.

Experiments of M. Girard.

25. The law of resistance discovered by Coulomb, was first applied to the determination of the velocity of running water by M. Girard, who considers the resistance as represented by a constant quantity, multiplied by the sum of the first and second powers of the velocity. He regards the water which moves over the wetted sides of the channel as at first retarded by its viscidity, and he concludes that the water will, from this cause, suffer a retardation proportional to the simple velocity. A second retardation, analogous to that of friction in solids, he ascribes to the roughness of the channel, and he represents it by the second power of the velocity, as it must be in the compound ratio of the force and the number of impulsions which the asperities receive in a given time. He then expresses the resistance due to cohesion by a constant quantity, to be determined experimentally, multiplied into the product of the velocity of the perimeter of the section of the fluid.

A.D. 1814.

26. The influence of heat in promoting fluidity was known to the ancients;[2] but M. Du Buat was the first person who investigated the subject experimentally. His results, however, were far from being satisfactory; and it was left to

[1] A third volume of this work was published in 1816, entitled *Principes d'Hydraulique et Pyrodynamique*, relating chiefly to the subject of heat and elastic fluids.

[2] Pliny, *Quæst. Nat.*

History.

M. Girard to ascertain the exact effect of temperature on the motion of water in capillary tubes. When the length of the capillary tube is great, the velocity is quadrupled by an increase of heat from 0° to 85° centig.; but when its length is small, a change of temperature exercises little or no influence on the velocity. He found also, that, in ordinary conduit pipes, a variation of temperature exercises scarcely any influence over the velocity.

Investigations of M. Prony, A.D. 1804.

27. The theory of running water was greatly advanced by the researches of M. Prony. From a collection of the best experiments by Couplet, Bossut, and Du Buat, he selected 82, of which 51 were made on the velocity of water in conduit pipes, and 31 on its velocity in open canals; and by discussing these on physical and mechanical principles, he succeeded in drawing up general formulæ, which afford a simple expression of the velocity of running water. The following is the formula for English feet, which answers both for pipes and canals:—

$$V = 0.1541131 + \sqrt{(0.023751 + 32806.6\,G)}$$

When we use this formula for canals, we must take $G = RI$, R being $= \frac{\omega}{\chi}$ and $I = \frac{\zeta}{\lambda}$, ω representing the area of the section of the pipe or canal, χ the perimeter of the section in contact with the water, ζ the difference of level between the two extremities of the pipe, and λ the length of the pipe or canal.

When the formula is applied to pipes, we must take $G = \frac{1}{4}DK$, D being the diameter of the pipe, and $K = \frac{H + \zeta}{\lambda}$, H being the height of the head of water above the superior orifice of the pipe.[1]

Researches of M. Eytelwein of Berlin, 1801.

28. M. Eytelwein of Berlin published, in 1801, a valuable compendium of Hydraulics, entitled *Handbuch der Mechanik und der Hydraulik*, which contains an account of many new and valuable experiments made by himself. His work is divided into 24 chapters, the most important of which are the 7th, which treats of the motion of water in rivers, and the 9th, which treats of the motion of water in pipes. He has shewn that the *mean velocity* of water in a second in a river or canal flowing in an equable channel, is $\frac{10}{11}$ths of a mean proportional between the fall in two English miles, and the hydraulic mean depth; and that the *superficial velocity* of a river is nearly a mean proportional between the hydraulic mean depth and the fall in two English miles. In treating of the motion of water in pipes, he obtains the following simple formula, which agrees wonderfully with experiment,

$$V = 50\sqrt{\left(\frac{dh}{l + 50\,d}\right)}$$

in which l is the length of the pipe, d the hydraulic mean depth, and h the height of the reservoir. The following are some of the other important results which are given in his work. The contraction of the fluid area is 0.64, the coefficient for additional pipes 0.65, the coefficient for a conical tube similar to the curve of contraction 0.98. For the whole velocity due to the height, the coefficient by its square must be multiplied by 8.0458. For an orifice, the coefficient must be multiplied by 7.8; for wide openings in bridges, sluices, &c. by 6.9; for short pipes 6.6; and for openings in sluices without side walls 5.1. Our author investigates the subject of the discharge of water by compound pipes, the motions of jets, and their impulses against plane and oblique surfaces, and he shews theoretically, that a water-wheel will have its effect a maximum when its circumference moves with half the velocity of the stream.

Mallet and Vici, A.D. 1809.

29. A series of interesting hydraulic experiments was made at Rome in 1809, by MM. Mallet and Vici.[2] They found that a pipe, whose gauge was *five ounces* French measure (or 0.03059 French kilolitres), furnished *one-seventh* more water than *five* pipes of *one* ounce, an effect arising from the velocity being diminished by friction in the ratio of the perimeters of the orifices as compared with their areas.

Researches of M. Poisson, 1816.

Notwithstanding the investigations of Newton, D'Alembert, and Lagrange, the problem of waves was still unsolved; and the Institute of France was induced to propose, as the subject of its annual prize for 1816, "The Theory of Waves on the surface of a heavy Fluid of indefinite depth." M. Poisson had previously studied this difficult subject, and he lodged his first memoir in the bureau of the Institute on the 2d October 1815, at the expiration of the period allowed for competition. M. Poisson supposes the waves to be produced in the following manner. A body of the form of an elliptic paraboloid is immersed a little in the fluid, with its axis vertical and its vertex downwards. After being left in this position till the equilibrium of the fluid is restored, the body is suddenly withdrawn, and waves are formed round the place which it occupied. This first memoir contains the general formula for waves propagated with an uniformly accelerated motion; but in a second memoir, read in December, he gives the theory of waves propagated with a constant velocity. This last class of waves are much more sensible than the first, and are those which are seen to spread in circles round any disturbance made at the surface of water. In determining the superficial as well as the internal propagation of these waves, he considers only the case when the disturbance of the water is so small, that the second and the higher powers of the velocity of the oscillating particles may be neglected; and he assumes, that a fluid particle which is at any instant at the surface, continues there during the whole of the motion, a supposition which the condition of the continuity of the fluid renders necessary. He supposes the depth of the water constant throughout its whole extent, the bottom being considered as a fixed horizontal plane at a given distance beneath its natural surface. He then treats, *first*, the case in which the motion takes place in a canal of uniform width, over which obstruction is made of the horizontal dimension of the fluid; and, *secondly*, the case in which the fluid is considered in its true dimensions.

Researches of M. Cauchy, 1816.

30. The prize offered by the Institute was gained by M. Augustin Louis Cauchy, then a young mathematician of the highest promise. In his memoir, which was published in the 3d volume of the *Mémoires des Sçavans*, he treats only of the first kind of waves above mentioned; and his investigation claims to be more complete than that in the first memoir of Poisson, in so far as it leaves entirely arbitrary the form of the function relative to the initial form of the fluid surface, and, therefore, allows the analysis to be applied when bodies of different forms are used to produce the initial disturbance. From his analysis, M. Cauchy concludes, "that the heights and velocities of the different waves produced by the immersion of a cylindrical or prismatic body, depend not only on the width and height of the part immersed, but also on the form of the surface which bounds this part." He is also of opinion, that the number of the waves produced may depend on the form of the immersed body, and the depth of immersion.

Results of theory respecting waves.

31. The following abstract of the principal results obtained by theory, respecting the nature of waves, has been given by Mr Challis:—

"With respect first to the canal of uniform width, the law of the velocity of propagation found by Lagrange, is

[1] See Prony's *Recherches Physico-mathématiques sur la Théorie des Eaux Courantes*.

[2] See Mallet, *Notices Historiques*; Paris, 1830.

History.

confirmed by Poisson's theory when the depth is small, but not otherwise.

"When the canal is of unlimited depth, the following are the chief results.

"1. An impulse given to any point of the surface, affects instantaneously the whole extent of the fluid mass.

"The theory determines the magnitude and direction of the initial velocity of each particle resulting from a given impulse.

"2. The summit of each wave moves with a uniformly accelerated motion.

"This must be understood to refer to a series of very small waves, called by M. Poisson *dents*, which perform their movements, as it were, on the surface of the larger waves, which he calls '*les ondes dentelées*.' Each wave of the series is found to have its proper velocity, independent of the primitive impulse.

"3. At considerable distances from the place of disturbance, there are waves of much more sensible magnitude than the preceding.

"Their summits are propagated with a uniform velocity, which varies as the square root of the breadth *à fleur d'eau* of the fluid originally disturbed. Yet the different waves which are formed in succession, are propagated with different velocities: the foremost travels swiftest. The amplitudes of oscillations of equal duration, are reciprocally proportional to the square root of the distances from the point of disturbance.

"4. The vertical excursions of the particles situated directly below the primitive impulse, vary according to the inverse ratio of the depth below the surface. This law of decrease is not so rapid but that the motion will be very sensible at very considerable depths: it will not be the true law, as the theory proves, when the original disturbance extends over the whole surface of the water, for the decrease of motion in this case will be much more rapid.

"The results of the theory, when the three dimensions of the fluid are considered, are analogous to the preceding 1, 2, 3, 4, and may be stated in the same terms, excepting that the amplitudes of the oscillations are inversely *as the distances* from the origin of disturbance, and the vertical excursions of the particles situated directly below the disturbance, vary inversely as the *square* of the depth."

Experiments of Weber and Bidone, 1825.

32. Several very interesting experiments on the propagation of waves, have been made by M. Weber and by M. Bidone. Although Weber's[1] experiments were not made in exact conformity with the condition which the theory required, yet they, generally speaking, harmonize with it; and they particularly establish the existence of the small accelerated waves near the place of disturbance, and of a perceptible motion of the particles of the fluid at considerable depths below the surface. When an elliptic paraboloid is used to produce the waves, with its axis vertical, and its vertex downwards, and when, of course, the section of the solid in the plane of the surface of the water is an ellipse, the velocity of propagation is, according to the theory, greater in the direction of the major axis than in that of the minor, in the ratio of the square root of the one to the square root of the other; but this result is not confirmed by Weber's experiments.

M. Bidone of Turin[2] has made experiments on waves more conformable to the condition of the theory, and he has in a great measure removed the obstacle arising from the adhesion of the water to the immersed body; and the experiments which he has thus made, confirm the laws of motion, as well as the existence of accelerated waves.

Investigations of M. Bidone, 1826–7.

33. In 1826, M. Bidone made a series of experiments on the velocity of running water at the hydraulic establishment of the University of Turin, and he published an account of them in 1829.[3] After giving a description of his apparatus and method of experimenting, he gives the figures obtained from fluid veins, discharged from rectilineal and curvilineal orifices with salient angles pierced in vertical plates, and whose perimeters are formed of straight and curve lines, varying in more than fifty different ways, with variable and invariable changes from zero to 22 French feet, the area of the water being equal to one square inch. The sections of the veins were taken at different distances from the orifice, and the results, which are extremely curious, are illustrated by diagrams.

In a subsequent memoir, M. Bidone gives a theoretical view of his experiments. He considers the greatest contraction of the fluid vein to take place at a distance not more than the greatest diameter of the orifice, whatever be its shape; and hence it follows, that the discharge from the orifice is equal to the sum of the product of each superficial element, multiplied by the velocity of the fluid vein; and since the area of the vena contracta was found to be from 0.60 to 0.62, the expenditure will be represented by the product of this coefficient of contraction, and the velocity due to the charge.

In the case of a fluid vein issuing from a small orifice relative to the section of the vessel, and reduced to a state of permanence, he finds that the area of the section of the vena contracta depends solely on the direction, and not on the velocity, of its component filaments; a result which experiment confirms. M. Bidone next ascertains that, in a circular orifice, the absolute diameter of the vena contracta is exactly two-thirds of that of the orifice, the correction which is due to the contraction depending on the adhesion and friction of the fluid against the perimeter of the orifice, and the ratio of the area of the vein to the area of the orifice; the same being true for all orifices.

Experiments of General Sabatier, 1827.

34. A series of useful experiments was made in 1827, under the sanction of the French government, by General Sabatier, Commandant of the Military School at Metz. The apparatus which he used consisted of *four* basins. The *first* had an area of 25,000 square metres: the *second* had an area of only 1500 square metres, and a depth of 3.70 metres, and was so contrived by means of sluices, as to have a complete command of the level of the water during the experiment: the *third* basin, which communicated directly with the second basin, was 3.68 metres long and 3 wide, to receive the water discharged by the orifices: and the *fourth* basin was a gauge capable of containing 24,000 litres. In carrying on the experiments, the opening of the orifices, the height or charge of the fluid in the reservoir, as well as the level of the water in the gauge basin relative to each discharge of fluid, were measured to the tenth of a millimetre, so that the approximation was at least $\frac{1}{200}$dth of the whole result.

The following are some of the principal results of these experiments.

1. For complete orifices of 20 centimetres square and high charges, the coefficient is 0.600. When the charge is 4 or 5 times the opening of the orifice, the coefficient becomes 0.605, but beyond that charge the coefficient diminishes to 0.593.

2. The same law takes place for 10 and 5 centimetres in height, the coefficients being for 10 centimetres 0.611, 0.618, 0.611, respectively, and for 5 centimetres in height 0.618, 0.631, 0.623.

3. With orifices of 3, 2, and 1, centimetres in height, the law changes rapidly, and the coefficients increase as the opening of the orifice diminishes, being for 1 centimetre, the smallest height of the orifice, 0.698 to 0.640 for 3 centimetres.

Mr George Rennie, 1830.

35. In the year 1830, Mr George Rennie undertook a series

[1] *Wellenlehre auf Experimente gegrundet.* Leipzig, 1825.

[2] *Turin Memoirs*, vol. xxv.

[3] *Expériences sur la forme et sur la direction des Veines et des Courans d'Eau, lancés par diverses ouvertures.*

of experiments on the friction of water against revolving cylinders and discs, on the direct resistances to globes and discs revolving in air and water alternately, on the coefficients of contraction, and on the expenditure of water through orifices, additional tubes, and pipes of different lengths. The following are some of his principal results.

1. It appears from his first series of experiments, that, with slow velocities, the friction varies with the surfaces; that an increase of surface did not materially affect the friction with increased velocities; and that, with equal surfaces, the resistances approximated to the squares of the velocities.

2. In the experiments on the resistances experienced by globes and discs revolving in air and water alternately, it appears that the resistances in both cases were as the squares of the velocities, and that the mean resistances were as follows:

		Resist. in Air.	Resist. in Water.
Circular discs,	.	25.180	1.18
Square plates,	.	22.010	1.36
Round globes,	.	10.627	0.75

3. In circular orifices in brass plates, $\frac{1}{66}$th of an inch thick, and with apertures of $\frac{1}{4}$, $\frac{1}{2}$, $\frac{1}{3}$, and $\frac{1}{1}$ of an inch respectively, under pressures from 1 to 4 feet, the coefficients were—

		Coefficient of contraction.
For altitudes of 1 foot,	.	0.619
.... 4 feet,	.	0.621

For additional tubes of glass, they were—

		Coefficient.
For altitudes of 1 foot,	.	0.817
.... 4 feet,	.	0.806

4. The expenditure through orifices, additional tubes, and pipes of different lengths, of equal areas, and the same kind of water, as compared with the expenditure through a pipe 30 feet long, are—

For orifices,	.	.	3 to 1
For additional tubes,	.	.	4 to 1
For a pipe 1 foot long,	.	.	3.7 to 1
.... 2 feet long,	.	.	1.4 to 1
.... 4 feet long,	.	.	2.0 to 1
.... 8 feet long,	.	.	2.6 to 1

5. With bent rectangular pipes, half an inch in diameter, and 15 feet long, the expenditure was diminished two-thirds; with 14 bends as compared with a straight pipe, and with 24 bends, one-third; but it did not seem to follow any law.

Experiments of Mr Jardine.

36. Many very accurate experiments on the discharge of water from long pipes, were made by James Jardine, Esq. civil-engineer. In the case of the Comiston Main, which conducts the water from the reservoir at Comiston to the Castle at Edinburgh, the length of the pipe is 14,930 feet, its diameter $4\frac{1}{2}$ inches, the altitude 51 feet, and the quantity of water actually delivered 189.4 Scots pints. This valuable result Mr Jardine compared with the different formulæ as follows:

		Scots pints.
Actual delivery of water at Comiston Main,	.	189.4
Calculated do. by Eytelwein's formula,	.	189.77
Do. by Gerard's formula,	.	188.26
Do. by Dubuat's formula,	.	188.13
Do. by Prony's simple formula,	.	182.32
Do. by Prony's tables,	. .	180.7

Improvement in theory of fluids by Mr Airy, 1830.

37. An improvement on the common theory of fluids was lately suggested by Professor Airy, in his lectures at Cambridge. It had been usual to assume the law of equal pressure as a datum of observation. Professor Airy, however, has shewn that this property may be deduced from another more simple and equally given by observation; namely, that the division of a perfect fluid may be effected without the application of sensible force; and hence, it immediately follows, that the state of equilibrium or motion of a mass of fluid, is not altered by a mere separation of its parts by an indefinitely thin partition. Professor Miller has given a definition of fluids founded on this principle, and a proof of the law of equal pressure, at the beginning of his *Elements of Hydrostatics*, &c. published at Cambridge in 1831. Dr Thomas Young had employed an equivalent principle to that of Mr Airy in determining the manner of the reflection of waves of water;[1] and Mr Challis considers it as necessary in the solution of some hydrostatical and hydrodynamical problems.

Researches of Prof. Mosely, 1830.

38. There are certain cases in the analytical theory of hydrodynamics which require a more simple analysis than others; such, for example, as those of *steady* motion, or of motion which has arrived at a permanent state, so that the velocity is constant in quantity and direction at the same point. Equations applicable to this kind of motion seem to have been first given by Professor Mosely, in his *Elementary Treatise on Hydrostatics and Hydrodynamics.* The following is the principle from which he has derived them. *When the motion is steady, each particle, in passing from one point to another, passes successively through the states of motion of all the particles which at any instant lie in its path.* This general principle is applicable to all kinds of fluids, and is true, whether or not the effect of heat is taken into account, provided the condition of steadiness remains. As it enables us to consider the motion of a single particle in place of that of a number, it readily affords the equations of motion.

Researches of Mr Challis.

39. As it was desirable to know how the same equation might be obtained from the general equations of fluid motion, Mr Challis undertook this inquiry, and published the results of it in the *Transactions of the Cambridge Philosophical Society.*[2] In this paper, he has given a method of doing this both for incompressible and elastic fluids, and he has shewn that a term in the general formulæ which occasions the complexity in most hydrodynamical questions, disappears in cases of steady motion. Mr Challis is of opinion, that these equations may be employed in very interesting researches, and he mentions, as instances, the motion of the atmosphere as affected by the rotation of the earth, and a given distribution of temperature due to solar heat.

Experiments of Eytelwein and others.

40. The science of hydrodynamics has of late years been cultivated by M. Eytelwein of Berlin, whose practical conclusions coincide nearly with those of Bossut; by Dr Matthew Young, late Bishop of Clonfert, who has explained the cause of the increased velocity of efflux through additional tubes; and by Mr Vince, Dr T. Young, Coulomb, and Don George Juan; but the limits of this work will not permit us to give any further account of their labours at present. We must now proceed to initiate the reader into the science itself, beginning with that branch of it which relates to the pressure, equilibrium, and cohesion of nonelastic fluids.

[1] *Nat. Phil.* vol. ii. p. 64.

[2] Vol. iii. Part iv.

PART I.—HYDROSTATICS.

Hydrostatics.

Definition of hydrostatics.

41. Hydrostatics is that branch of the science of hydrodynamics which comprehends the pressure and equilibrium of non-elastic fluids, as water, oil, mercury, &c.; the method of determining the specific gravities of substances, the equilibrium of floating bodies, and the phenomena of capillary attraction.

DEFINITIONS AND PRELIMINARY OBSERVATIONS.

Definition of a fluid.

42. A fluid is a collection of very minute particles, cohering so little among themselves, that they yield to the smallest force, and are easily moved among one another.

Perfect fluids.

Imperfect fluids.

43. Fluids have been divided into *perfect* and *imperfect.* In perfect fluids the constituent particles are supposed to be endowed with no cohesive force, and to be moved among one another by a pressure infinitely small. But, in imperfect or viscous fluids, the mutual cohesion of their particles is very sensible, as in oil, varnish, melted glass, &c.; and this tenacity prevents them from yielding to the smallest pressure. Although water, mercury, alcohol, &c. have been classed among perfect fluids, yet it is evident that neither these nor any other liquid is possessed of perfect fluidity. When a glass vessel is filled with water above the brim, it assumes a convex surface; and when a quantity of it is thrown on the floor, it is dispersed into a variety of little globules, which can scarcely be separated from one another. Even mercury, the most perfect of all the fluids, is endowed with such a cohesive force among its particles, that if a glass tube, with a small bore, is immersed in a vessel full of this fluid, the mercury will be lower in the tube than the surface of the surrounding fluid;—if a small quantity of it be put in a glass vessel, with a gentle rising in the middle of its bottom, the mercury will desert the middle, and form itself into a ring, considerably rounded at the edges; or if several drops of mercury be placed upon a piece of flat glass, they will assume a spherical form; and if brought within certain limits, they will conglobulate and form a single drop. Now, all these phenomena concur to prove, that the particles of water have a mutual attraction for each other; that the particles of mercury have a greater attraction for one another, than for the particles of glass; and, consequently, that these substances are not entitled to the appellation of perfect fluids.

Florentine experiment.

Compressibility of water first noticed by Lord Bacon.

44. It was universally believed, till within the last seventy years, that water, mercury, and other fluids of a similar kind, could not be made to occupy a smaller space, by the application of any external force. This opinion was founded on an experiment made by Lord Bacon, who inclosed a quantity of water in a leaden globe, and by applying a great force attempted to compress the water into a less space than it occupied at first: The water, however, made its way through the pores of the metal, and stood on its surface like dew. The same experiment was afterwards repeated at Florence by the Academy del Cimento, who filled a silver globe with water, and hammered it with such force as to alter its form, and drive the water through the pores of the metal. Though these experiments were generally reckoned decisive proofs of incompressibility, yet Bacon himself seems to have drawn from his experiment a very different conclusion; for after giving an account of it, he immediately adds, that *he computed into how much less space the water was driven by this violent pressure.*[1] This passage from Lord Bacon does not seem to have been noticed by any writer on hydrostatics, and appears a complete proof that the compressibility of water was fairly deducible from the issue of his experiment. In consequence of the reliance which was universally placed on the result of the Florentine experiment, fluids have generally been divided into *compressible* and *incompressible,* or *elastic* and *non-elastic fluids:* water, oil, alcohol, and mercury, being regarded as incompressible and non-elastic; and air, steam, and other aëriform fluids, as compressible or elastic.

Fluids divided into compressible and incompressible.

Compressibility of water ascertained by Mr Canton,

45. About the year 1761, the ingenious Mr Canton began to consider this subject with attention, and distrusting the result obtained by the Academy del Cimento, resolved to bring the question to a decisive issue.[2] Having procured a small glass tube, about two feet long, with a ball at one end, an inch and a quarter in diameter, he filled the ball and part of the tube with mercury, and brought it to the temperature of 50° of Fahrenheit. The mercury then stood six inches and a half above the ball; but after it had been raised to the top of the tube by heat, and the tube sealed hermetically, then, upon bringing the mercury to its former temperature of 50°, it stood $\frac{32}{100}$th of an inch higher in the tube than it did before. By repeating the same experiment with water exhausted of air, instead of mercury, the water stood $\frac{43}{100}$th of an inch higher in the tube than it did at first. Hence, it is evident, that when the weight of the atmosphere was removed, the water and mercury expanded, and that the water expanded $\frac{11}{100}$th of an inch more than the mercury. By placing the apparatus in the receiver of a condensing engine, and condensing the air in the receiver, he increased the pressure upon the water, and found that it descended in the tube. Having thus ascertained the fact, that water and mercury are compressible, he subjected other fluids to similar experiments, and obtained the results in the following table:

	Millionth Parts.	Specific Gravity.
Compression of Mercury,..........	3	13.595
Sea-Water,........	40	1.028
Rain-Water,......	46	1.000
Oil of Olives,.....	48	0.918
Spirit of Wine,...	66	0.846

Lest it should be imagined that this small degree of compressibility arose from air imprisoned in the water, Mr Canton made the experiment on some water which had imbibed a considerable quantity of air, and found that its compressibility was not in the least augmented. By inspecting the preceding table, it will be seen that the compressibility of the different fluids is nearly in the inverse ratio of their specific gravities.

and confirmed by Zimmerman.

46. The experiments of Mr Canton have been lately confirmed by Professor Zimmerman. He found that sea-water was compressed $\frac{1}{340}$th part of its bulk, when inclosed in the cavity of a strong iron cylinder, and under the influence of a force equal to a column of sea-water 1000 feet in height. From these facts, it is obvious that fluids are susceptible of contraction and dilatation, and that there is no foundation in nature for their being divided into compressible and incompressible. If fluids are compressible, they will also be elastic; for when the compressing force is removed, they will recover their former magnitude; and

[1] *Bacon's Works,* by Shaw, vol. ii. p. 521; *Novum Organum,* part. ii. sect. 2. alph. 45. § 222.

[2] See the *Philosophical Transactions* for 1762 and 1764, vols. lii. and liv.

Pressure, &c. of fluids.

hence their division into elastic and non-elastic is equally improper.

Experiments of Professor Oersted.

A series of very valuable experiments on the compressibility of water has recently been made by Professor Oersted of Copenhagen. At the temperature at which water has a maximum density, which, according to Professor Stampfer of Vienna, is at 38° 75 of Fahrenheit, Professor Oersted found the *true* compressibility of water by one atmosphere (or 336 French lines of mercury) to be 46.1 millionths of the volume, the difference between the true and the apparent compressibility arising from the effect of the heat developed by the compression, by which the liquid and the bottle are dilated. He found also that the differences of volume in the compressed water are proportional to the compressing power; and that this law holds as far as the pressure of 65 atmospheres, and probably much farther; but how far he was not able to determine, as his apparatus could not resist a greater pressure.

Experiments of Mr Perkins.

A series of interesting experiments at high pressures were made by Mr Perkins, who has described the instrument which he employed in the *Philosophical Transactions* for 1826, p. 541. The following table contains the results which he obtained from 10 to 2000 atmospheres upon a column of water 190 inches long:

Pressure, &c. of Fluids.

No. of Atmospheres.	Compression. Inch.	No. of Atmospheres.	Compression. Inch.	No. of Atmospheres.	Compression. Inch.
10	0.189	80	1.187	500	5.087
20	0.372	90	1.288	600	5.907
30	0.547	100	1.422	700	6.715
40	0.691	150	1.914	800	7.402
50	0.812	200	2.440	900	8.243
60	0.756	300	3.339	1000	9.002
70	1.056	400	4.193	2000	15.833

If the number of atmospheres are made the abscissa of a curve, and the compressions its ordinates, it will be seen that the curve approximates to a hyperbolic one.

47. The doctrines of hydrostatics have been deduced by different philosophers from different properties of fluids. Euler has founded his analysis on the following property, "that when fluids are subjected to any pressure, that pressure is so diffused throughout the mass, that when it remains in equilibrio all its parts are equally pressed in every direction."[1] D'Alembert at first[2] deduced the principles of hydrostatics from the property which fluids have of rising to the same altitude in any number of communicating vessels; but he afterwards[3] adopted the same property as Euler from the foundation which it furnishes for an algebraical calculus. The same property has been employed by Bossut, Prony, and other writers, and will form the first proposition of the following chapter.

CHAPTER I.—ON THE PRESSURE AND EQUILIBRIUM OF FLUIDS.

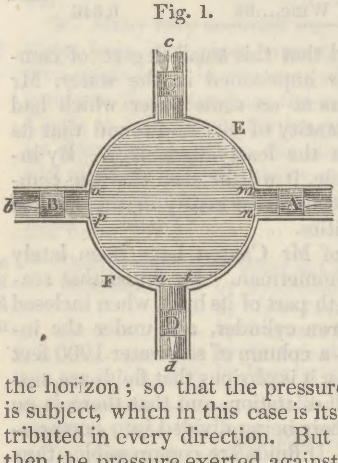
Proposition I.

48. When a mass of fluid, supposed without weight, is subjected to any pressure, that pressure is so diffused throughout the whole, that when it remains in equilibrio all its parts are equally pressed in every direction.

The parts of a fluid subjected to any pressure, are equally pressed in every direction.

As it is the distinguishing property of fluids that their particles yield to the smallest pressure, and are easily moved among themselves (26.), it necessarily follows, that if any particle is more pressed towards one side than towards another, it will move to that side where the pressure is least; and the equilibrium of the fluid mass will be instantly destroyed. But by the hypothesis the fluid is in equilibrio, consequently the particle cannot move towards one side, and must therefore be equally pressed in every direction.

Fig. 1.



In order to illustrate this general law, let EF (fig. 1.) be a vessel full of any liquid, and let *mn*, *op* be two orifices at equal depths below its surface; then, in order to prevent the water from escaping, it will be necessary to apply two pistons, A and B, to the orifices *mn*, *op* with the same force, whether the orifice be horizontal or vertical, or in any degree inclined to the horizon; so that the pressure to which the fluid mass is subject, which in this case is its own gravity, must be distributed in every direction. But if the fluid has no weight, then the pressure exerted against the fluid at the orifice *op*, by means of the piston B, will propagate itself through every part of the circular vessel EF, so that if the orifices *mn*, *tu* are shut, and *rs* open, the fluid would rush through this aperture, in the same manner as it would rush through *mn* or *tu*, were all the other orifices shut. This proposition, however, is true only in the case of perfect fluids; for when there is a sensible cohesion between the particles, as in water, an equilibrium may exist even when a particle is less pressed in one direction than in another; but this inequality of pressure is so exceedingly trifling, that the proposition may be considered as true, even in cases of imperfect fluidity.

Prop. II.

49. If to the equal orifices *mn*, *tu*, *op*, *rs* of a vessel, containing a fluid destitute of weight, be applied equal powers A, B, C, D, in a perpendicular direction, or if the orifices *mn*, &c. be unequal, and the powers A, B, &c. which are respectively applied to them be proportional to the orifices, these powers will be in equilibro. Fig. 1.

It is evident from the last proposition, that the pressure exerted by the power B is transmitted equally to the orifices *mn*, *rs*, *tu*, that the pressure of the power C is transmitted equally to the orifices *mn*, *op*, *tu*, and so on with all other powers. Every orifice then is influenced with the same pressure, and, consequently, none of the powers A, B, C, D, can yield to the action of the rest. The fluid mass, therefore, will neither change its form nor its situation, and the powers A, B, C, D will be in equilibro. If the powers A, B, C, D are not equal to one another, nor the orifices *mn*, *op*, *rs*, *tu*; but if $A : B = mn : op$, and so on with the rest, the fluid will still be in equilibrio. Let A be greater than B, then *mn* will be greater than *op*; and whatever number of times B is contained in A, so many times will *op* be contained in *mn*. If $A = 2B$, then $mn = 2\,op$, and since the orifice *mn* is double of *op*, the pressure upon it must also be double; and, in order to resist that pressure, the power A must also be double of B;

[1] *Nov. Comment. Petropol.* tom. xiii. p. 305.

[5] *Traité des Fluides*, § 20.

[2] *Mélanges de Littéarture, d'Histoire, et Philosophie.*

Pressure, &c. of Fluids.

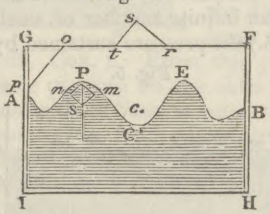
but, by hypothesis, A = 2 B, consequently the pressures upon the orifices, or the powers A, B, will be in equilibrio. If the power A is any other multiple of B, it may be shewn in the same way that the fluid will be in equilibrio.

Prop. III.

50. The surface of a fluid, influenced by the force of gravity and in equilibrio in any vessel, is horizontal, or at right angles to the direction of gravity.

The surface of fluids horizontal.

Fig. 2.



Let the surface of the fluid be supposed to assume the waving form APEB. Any particle P in the surface of the fluid is influenced by the force of gravity, which may be represented by PS, and which may be decomposed into two forces P*m*, P*n* in the direction of the two elementary portions of the surface P*m*, P*n* (see Article Dynamics). But since the particle P is in a state of equilibrium, the force of gravity acting in the direction P*m*, P*n* must be destroyed by equal and opposite forces, exerted by the neighbouring particles against P in the direction *m*P, *n*P; therefore the forces P*m*, P*n* are equal to the forces *m*P, *n*P. Now the particle P being in equilibrio, must be equally pressed in every direction (48). Wherefore the forces P*m*, P*n* are equal, and by the doctrine of the composition of forces (see Article Dynamics), the angle *m* P*n* formed by the two elementary portions P*m*, P*n* of the surface of the fluid, must be bisected by PS, the line which represents the direction of gravity. The same may be proved of every other point of the surface of the fluid; and therefore this surface must be horizontal or perpendicular to the direction of gravity.

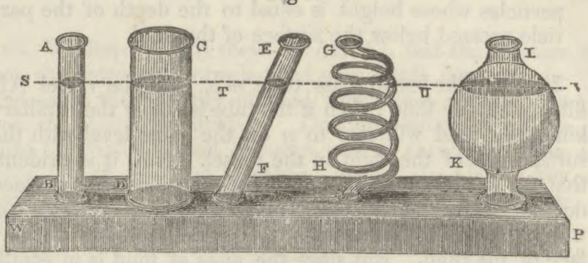
51. This proposition may be otherwise demonstrated. From the principles of mechanics, it is obvious, that when the centre of gravity of any body is at rest, the body itself is at rest; and that when this centre is not supported, the body itself will descend, till it is prevented by some obstacle from getting farther. In the same manner the centre of gravity of a fluid mass will descend to the lowest point possible; and it can be shewn that this centre will be in its lowest position only when the surface of the fluid mass is horizontal. For let FGHI (fig. 2) be any surface, whether solid or fluid, and C its centre of gravity, the point C is nearer the line HI when FG is parallel to HI and rectilineal, than when it has any other form or position. When the surface FGHI is suspended by the point C, or balanced upon it, it will be in equilibrio; but if the line FG is made to assume any other form as F*rstop*, by removing the portion G*op* of the surface to *rst*, the equilibrium, will be destroyed, and the side FG will preponderate. In order, therefore, to restore the equilibrium, the surface must be balanced on a point *c* farther from HI; that is, the centre of gravity of the surface F*rstop*IH is *c*. In the same way it may be shewn, that whatever be the form of the bounding line FG, the quantity of surface remaining the same, its centre of gravity will be nearest HI, when FG is rectilineal and parallel to it. On the truth contained in this proposition depends the art of levelling, and the construction of the spirit level, for an account of which see Levelling.

52. As the direction of gravity is in lines which meet near the centre of the earth; and as it appears from this proposition, that the surface of fluids is perpendicular to that direction, their surface will be a portion of a spheroid similar to the earth. When the surface has no great extent, it may be safely considered as a plane; but when it is pretty large, the curvature of the earth must be taken into account.

Prop. IV.

53. The surface of a fluid influenced by the force of gravity, and contained in any number of communicating vessels, however different in form and position, will be horizontal.

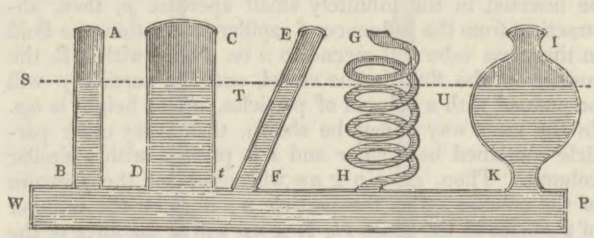
Fig 3.



The surface of a fluid in any number of communicating vessels is horizontal.

Let AB, CD, EF, GH, IK, be a system of communicating vessels into which a quantity of fluid is conveyed: It will rise to the same height in each vessel, and have a horizontal surface. Suppose ABEF, fig. 4, a vessel full of water. By the last proposition, its surface ST will be horizontal. Now, if any body be plunged into this vessel, the cylinder AD for instance, the surface of the fluid will still be horizontal; for no reason could be assigned for the water's rising on one side of this body any more than on another. Let us now immerge into the fluid, successively, the solid bodies AD, CE*t*, GHF, &c., then after each immersion the surface will still be horizontal; and when all these solids are immerged, the large vessel ABFE will be converted into the system of communicating vessels represented in fig. 4, in which the surface of the fluid will, of consequence, be horizontal.

Fig. 4.



54. This proposition may be also demonstrated by supposing the parts AD, CE*t*, GHF, &c. converted into ice without changing their former magnitude. When this happens, the equilibrium will not be disturbed; and the fluid mass AF, whose surface was proved to be horizontal by the last proposition, will continue in the same state after the congelation of some of its parts. That is, the surface of the fluid in the communicating vessels will be horizontal.

This proposition is not true when the communicating vessels are capillary tubes.

55. When the communicating vessels are so small that they may be regarded as capillary tubes, the surface of the fluid will not be horizontal. From the attraction which all fluids have for glass, they rise to a greater height in smaller tubes than in larger ones, and the quantity of elevation is in the inverse ratio of the diameters of the bores. In the case of mercury, and probably of melted metals, the fluid substance is depressed in capillary tubes, and the depression is subject to the same law. The subject of capillary attraction will be treated at length in a subsequent part of this article.

56. This proposition explains the reason why the surface of small pools in the vicinity of rivers is always on

Pressure, &c. of Fluids.

a level with the surface of the rivers themselves, when there is any subterraneous communication between the river and the pool. The river and the pool may be considered as communicating vessels.

Prop. V.

57. If a mass of fluid contained in a vessel be in equilibrio, any particle whatever is equally pressed in every direction, with a force equal to the weight of a column of particles whose height is equal to the depth of the particle pressed below the surface of the fluid.

Fig. 5.

Immerse the small glass-tube *mp*, into the vessel AB filled with any fluid; then if the tube is not of the capillary kind, the fluid will rise to *n* on the same level with the surface AB of the fluid in the vessel. Now it is evident, that the particle *p* at the bottom of the tube *mp* is pressed downwards by the superincumbent column of particles *np*, which is equal to the depth of the particle *p* below the surface of the fluid. But since the mass of fluid is in equilibrio, the particle *p* is pressed equally in every direction: Therefore, the particle *p* is pressed equally in every direction by a force equal to the superincumbent column *np*.

Prop. VI.

58. A very small portion of a vessel of any form, filled with a fluid, is pressed with a force which is in the compound ratio of the number of particles contained in that surface, its depth below the surface of the fluid, and the specific gravity of the fluid.

Fig. 5.

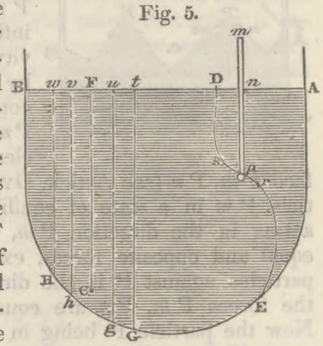
Let D*p* EB be the vessel, and *rs* a very small portion of its surface, the pressure upon *rs* is in the compound ratio of the number of particles in *rs*, and *np* its depth below the horizontal surface DB. Suppose the glass tube *mp* to be inserted in the infinitely small aperture *p*, then, abstracting from the influence of capillary attraction, the fluid in the glass tube will ascend to *n* on a level with DB, the surface of the fluid in the vessel, and the particle *p* will be pressed with a column of particles, whose height is *np*. In the same way it may be shewn, that every other particle contained between *r* and *s* is pressed with a similar column. Then, since $p \times np$ will represent the pressure of the column *np* on the particle *p*; if N be the number of particles in the space *rs*, $N \times np$ will be the force of the column supported by the space *rs*. And as the weight of this column must increase with the specific gravity of the fluid, $S \times N \times np$ will represent its pressure, S being the specific gravity of the fluid.

Prop. VII.

59. The pressure upon a given portion of the bottom of a vessel, whether plane or curved, filled with any fluid, is in the compound ratio of the area of that portion, and the *mean altitude* of the fluid, that is, the perpendicular distance of the centre of gravity of the given portion from the surface of the fluid; or, in other words, the pressure is equal to the weight of a column of fluid whose base is equal to the area of the given portion, and whose altitude is the mean altitude of the fluid.

Let AEGB be the vessel, and AFB the surface of the fluid which it contains. Let GH be a given portion of its bottom, and C the centre of gravity of that portion: Then shall CF be the mean altitude of the fluid. For, conceive the portion GH to be divided into an infinite number of small elements H*h*, G*g*, &c. then (58.) the pressure sustained by the elements H*h*, G*g*, will be respectively $S \times Hh \times Hw$; $S \times Gg \times Gt$, &c. the specific gravity of the fluid being called S. But it follows from the nature of the centre of gravity, that the sum of all these products is equal to the product of the whole portion GH into CF the distance of its centre of gravity from the horizontal surface of the fluid.[1] Therefore the pressure upon the portion GH is in the compound ratio of its surface converted into a plane, and the mean altitude of the fluid.

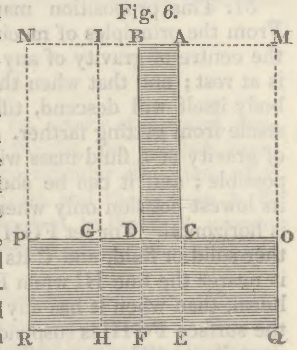
Fig. 5.



Hydrostatic paradox.

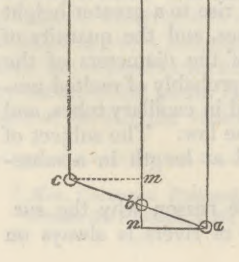
60. From this proposition we may deduce what is generally called the *Hydrostatic paradox*, viz. that *the pressure upon the bottoms of vessels filled with fluid does not depend upon the quantity of fluid which they contain, but upon its altitude*; or, in other words, *that any quantity of fluid, however small, may be made to balance any quantity or any weight, however great*. Let ACOQRPDB be a vessel filled with water, the bottom QR will sustain the same pressure as if it supported a quantity of water equal to MQRN. It is evident (59.) that the part EF is pressed with the column of fluid ABEF, and that the part DG equal to CD is pushed upwards with the weight of a column equal to ABCD. Now, as action and reaction are equal and contrary, the part DG reacts upon FH with a force equal to the weight of the column ABCD, and FH evidently sustains the smaller column DGFH; therefore FH sustains a pressure equal to the weight of the two columns ABCD and DGFH, that is, of the column BIHF. In the same way it may be shewn, that any other equal portion of the bottom QR sustains a

Fig. 6.



[1] This will be evident from the following proposition. *If every indefinitely small part of a surface be multiplied by its perpendicular distance from a given plane, the sum of the products will be equal to the product of the whole surface, multiplied by the perpendicular distance of its centre of gravity from the same plane.* In Fig. 7, let *a*, *c*, represent two weights suspended at their centre of gravity by the lines *a*A, *c*C, attached to the horizontal plane of which ABC is a section, and let *b* be the common centre of gravity of these weights, and *b*B the distance of this centre from the given plane, then $a \times aA + c \times cC = \overline{a+c} \times bB$.—Draw *an*, *cm*, at right angles to *b*B. Then since *b* is the common centre of gravity of the weights *a*, *c*, we shall have by the similar triangles *anb*, *cmb*, (Euclid, vi. 4.) $nb : mb = (ba : bc =) c : a$ (See Mechanics, Centre of Gravity). Hence $a \times nb = c \times mb$, or $a \times nB - bB = c \times bB - mB$, or $a \times nb - a \times bB = c \times bB - c \times mB$; then, by transposition, $a \times nb - c \times mB = a \times bB + c \times bB = \overline{a + C} + bB$. But $nB = aA$ and $mB = cC$, therefore, by substitution, $a \times aA + c \times cC = \overline{a+c} \times bB$. By supposing the two weights *a* and *c* united in their common centre of gravity, the same demonstration may be extended to any number of weights.

Fig. 7.

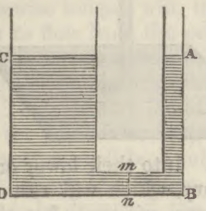


Pressure, &c. of Fluids.

similar pressure; and therefore it follows, that the pressure upon the bottom QR is as great as if it supported the whole column MNQR.

61. The same truth may be deduced from Prop. IV. For since the fluid in the two communicating vessels AB, CD, will rise to the same level, whatever be their size, the fluid in AB evidently balances the fluid in CD; and any surface *mn* is pressed with the same force in the direction B*m* by the small column AB, as it is pressed in the direction D*m* by the larger column CD.

Fig. 8.



Corollaries.

62. Cor. i. From this proposition it follows, that the whole pressure on the sides of a vessel which are perpendicular to its base, is equal to the weight of a rectangular prism of the fluid, whose altitude is that of the fluid, and whose base is a parallelogram, one side of which is equal to the altitude of the fluid, and the other to half the perimeter of the vessel.

Cor. ii. The pressure on the surface of a hemispherical vessel full of fluid, is equal to the product of its surface multiplied by its radius.

Cor. iii. In a cubical vessel the pressure against one side is equal to half the pressure against the bottom; and the pressure against the sides and bottom together, is to that against the bottom alone as three to one. Hence, as the pressure against the bottom is equal to the weight of the fluid in the vessel, the pressure against both the sides and bottom will be equal to three times that weight.

Cor. iv. The pressure sustained by different parts of the side of a vessel are as the squares of their depths below the surface; and if these depths are made the abscissæ of a parabola, its ordinates will indicate the corresponding pressures.

Definition.

Definition.

63. The *centre of pressure* is that point of a surface exposed to the pressure of a fluid, to which, if the total pressure were applied, the effect upon the plane would be the same as when the pressure was distributed over the whole surface: Or, it is that point to which, if a force equal to the total pressure were applied in a contrary direction, the one would exactly balance the other, or, in other words, the force applied and the total pressure would be *in equilibrio*.

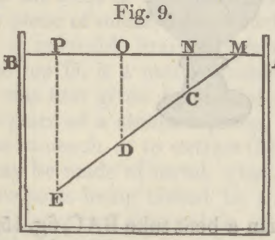
Prop. VIII.

64. The centre of pressure coincides with the centre of percussion.

To find the centre of pressure.

Let AB be a vessel full of water, and CE the section of a plane whose centre of pressure is required. Prolong CE till it cuts the surface of the water in M. Take any point D, and draw DO, EP, CN, perpendicular to the surface MP. Then if M be made the axis of suspension of the plane CE, the centre of percussion of the plane CE revolving round M will also be the centre of pressure. If MCE moves round M as a centre, and strikes any object, the percussive force of any point C is as its velocity, that is, as its distance CM from the centre of motion; therefore the percussive force of the points C, D, E, are as the lines CM, DM, EM. But the pressures upon the point C, D, E, are as the lines CN, DO, EP, and these lines are to one another as CM, DM, EM; therefore the percussive forces of the points C, D, E, are as the pressures upon these points. Consequently, the centre of pressure will always coincide with the centre of percussion.

Fig. 9.



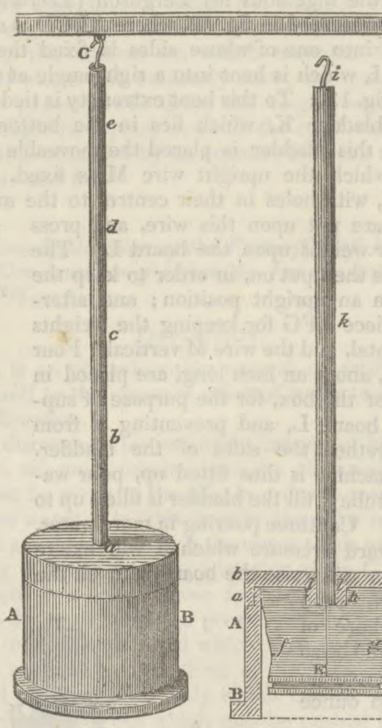
Pressure, &c. of Fluids.

Sect. II. *Instruments and Experiments for illustrating the Pressure of Fluids.*

Machine for illustrating the hydrostatic paradox. Fig. 10.

65. We have already shewn in Art. 57, that the pressure upon the bottoms of vessels filled with fluids does not depend upon the quantity of fluid which they contain, but upon its particular altitude. This proposition has been called the Hydrostatical Paradox, and is excellently illustrated by the following machine. In fig. 10, AB is a box which contains about a pound of water, and *abcd* a glass tube fixed to the end C of the beam of the balance, and the other end to a moveable bottom which supports the water in the box, the bottom and wire being of an equal weight with an empty scale hanging at the other end of the balance. If one pound weight be put into the empty scale, it will make the bottom rise a little, and the water will appear at the bottom of the tube *a*, consequently it will press with a force of one pound upon the bottom. If another pound be put into the scale, the water will rise to *b*, twice as high as the point *a*, above the bottom of the vessel. If a third, a fourth, and a fifth pound be put successively into the scale, the water will rise at each time to *c*, *d*, and *e*,

Fig. 10. Fig 11.



the divisions *ab*, *bc*, *cd*, *de*, being all equal. This will be the case, however small be the bore of the glass tube; and since, when the water is at *b*, *c*, *d*, *e*, the pressures upon the bottom are successively twice, thrice, four times, and five times as great as when the water was contained within the box, we are entitled to conclude that the pressure upon the bottom of the vessel depends altogether on the altitude of the water in the glass tube, and not upon the quantity it

Pressure, &c. of Fluids.

contains. If a long narrow tube full of water, therefore, be fixed in the top of a cask likewise full of water, then though the tube be so small as not to hold a pound of the fluid, the pressure of the water in the tube will be so great on the bottom of the cask, as to be in danger of bursting it; for the pressure is the same as if the cask was continued up in its full size to the height of the tube, and filled with water.

The smallest quantity of water may exert a force equal to any assignable one.

Upon this principle it has been affirmed that a certain quantity of water, however small, may be rendered capable of exerting a force equal to any assignable one, by increasing the height of the column, and diminishing the base on which it presses. This, however, has its limits; for when the tube becomes so small as to belong to the capillary kind, the attraction of the glass will support a considerable quantity of the water it contains, and therefore diminish the pressure upon its base.

Construction of the preceding machine.

Fig. 11.

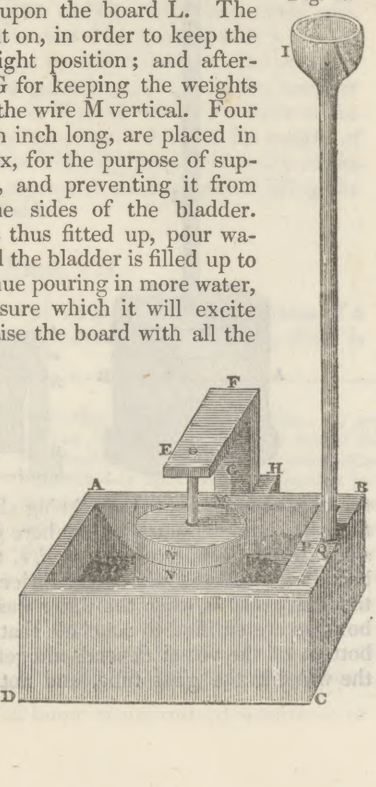
66. The preceding machine must be so constructed, that the moveable bottom may have no friction against the inside of the box, and that no water may get between it and the box. The method of effecting this will be manifest from fig. 11, where ABCD is a section of the box, and *abcd* its lid, which is made very light. The moveable bottom E, with a groove round its edges, is put into a bladder *fg*, which is tied close around it in the groove by a strong waxed thread. The upper part of the bladder is put over the top of the box at *a* and *d* all around, and is kept firm by the lid *abcd*, so that if water be poured into the box through the aperture *ll* in its lid, it will be contained in the space *f*E*gh*, and the bottom may be raised by pulling the wire *i* fixed to it at E.

The upward pressure of fluids illustrated by the hydrostatic bellows.

Fig. 12, 13.

67. The upward pressure of fluids is excellently illustrated by the hydrostatic bellows. The form given to this machine by the ingenious Mr Ferguson (*Lectures*, vol. ii. p. 111) is represented in fig. 12, where ABCD is an oblong square box, into one of whose sides is fixed the upright glass tube *a*I, which is bent into a right angle at the lower end as at *i*, fig. 13.: To this bent extremity is tied the neck of a large bladder K, which lies in the bottom of the box. Over this bladder is placed the moveable board L, fig. 14, in which the upright wire M is fixed. Leaden weights NN, with holes in their centre, to the amount of 16 pounds, are put upon this wire, and press with all their weight upon the board L. The cross bar P is then put on, in order to keep the glass tube in an upright position; and afterwards the piece EFG for keeping the weights N, N horizontal, and the wire M vertical. Four upright pins, about an inch long, are placed in the corners of the box, for the purpose of supporting the board L, and preventing it from pressing together the sides of the bladder. When the machine is thus fitted up, pour water into the tube I till the bladder is filled up to the board L. Continue pouring in more water, and the upward pressure which it will excite in the bladder will raise the board with all the weights NN, even though the bore of the tube should be so small as to contain no more than an ounce of water.

Fig. 12.



Experiment shewing tha the pressure of fluids arises from their gravity, and is propagated in every direction.

68. That the pressure of fluids arises from their gravity, and is propagated in every direction, may be proved by the following experiment. Insert into an empty vessel a number of

Fig. 13.

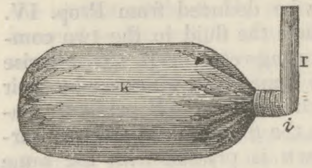


Fig. 14.

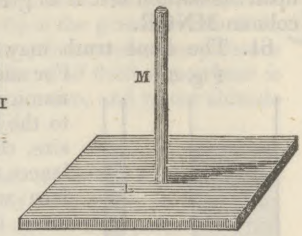


Pressure, &c. of Fluids.

glass tubes bent into various angles. Into their lower orifices introduce a quantity of mercury, which will rest in the longer legs on a level with these orifices. Let the vessel be afterwards filled with water; and it will be seen, while the vessel is filling, that the mercury is gradually pressed from the lower orifices towards the higher, where the water is prevented from entering. Now, in consequence of the various angles into which the glass tubes are bent, the lower orifices point to almost every direction; and therefore it follows, that the pressure of the superincumbent water is propagated in every direction. When a straight tube is employed to shew the upward pressure of fluids, the mercury which is introduced into its lower extremity must be kept in by the finger till the height of the water above the orifice is equal to fourteen times the length of the column of quicksilver: When the finger is removed the mercury will ascend in the tube.

Experiment shewing that the superior press upon the inferior strata of fluids.

69. The pressure of the superior strata of fluids upon the inferior strata may be shewn in the following manner. Immerse two tubes of different bores, but not of the capillary kind, in a vessel of mercury. The mereury will rise in the tube on a level with its surface in the vessel. Let water then be poured upon the mercury so as not to enter the upper orifices of the tubes, the pressure of the water upon the inferior fluid will cause the mercury to ascend in the tubes above the level of that in the vessel, but to the same height in both tubes. The columns of quicksilver in the two tubes are evidently supported by the pressure of the water on the inferior fluid. The same experiment may be made with oil and tinged water, the latter being made the inferior fluid.

Description of the common syphon.

70. The syphon is an instrument which shews the gravitation of fluids, and is frequently employed for decanting

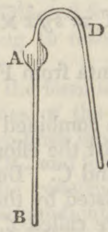
Fig. 15.

liquors. It is nothing more than a bent tube BAC, fig. 15, having one of its legs longer than the other. The shorter leg AC is immersed in the fluid contained in the vessel M; and if, by applying the mouth to the orifice B, the air be sucked out of the tube, the water in the vessel M will flow off till it be completely emptied. Now, it is obvious, that the atmosphere which has a tendency to raise the water in the shorter leg AC by its pressure on the surface ressure, &c. of Fluids.

of the water at M, has the same tondency to prevent the water from falling from the orifice B, by its pressure there, and therefore if the syphon had equal legs, no water could possibly issue from the orifice. But when the leg AB is longer than AC, the column of fluid which it contains being likewise longer, will, by its superior weight, cause the water to flow from the orifice B, and the velocity of the issuing fluid will increase as the difference between the two legs of the syphon is made greater.

The syphon is greatly improved by fixing a stop-cock D at the end of the longer branch, and placing on the same branch a small bent tube DE, communicating with the tube AB above D. When the aperture C is placed in the water to be drawn off, the mouth of the stop-cock D is closed, and the air is drawn out by suction at E from the longer branch. When there is no stop-cock at D, the finger may be applied there, till the air is sucked out at E.

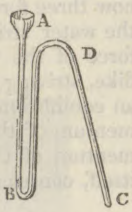
Fig. 16.



unten's phon.

An improved syphon by M. Bunten is shewn in fig. 16. where a bulb A is placed on the long branch AB. This syphon requires neither to be blown into nor sucked. When the long branch AB and bulb A are filled with fluid, and the other branch plunged in the fluid, the flow will be unremitting, as the bulb A in emptying itself draws off the liquid in contact with the short branch.

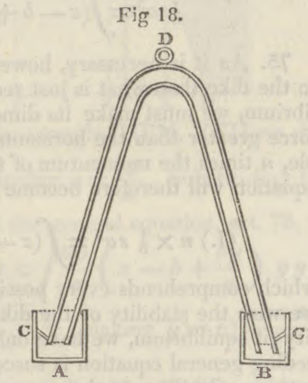
Fig. 17.



empel's proved phon.

Another improvement on the syphon is shewn in fig. 17. as made by M. Hempel of Berlin. The short branch has fitted into it a vertical tube BA, terminating in a funnel A. A part of the liquid to be drawn off is then poured into the funnel A, and as soon as the flow commences the long branch DC, the tube AB is withdrawn, and the flow continues.

Fig 18.



unter's taining yphon.

Another improvement on the syphon made by Mr Hunter of Thurston, is shewn in fig. 18. which has the peculiar advantage of retaining its charge. Two small cups or boxes A, B are fixed to the ends of the unequal branches by two screws C, C. When it is charged in the common way, and has been in use, it will stand vertically in the boxes A, B as a base, so that, when it is lifted by the ring D, it may be replaced, and will act as before. The same effect may be obtained by turning up the ends of the branches, and fixing to them a plate or piece of metal, upon which they may stand.

Ioveable ranch yphon.

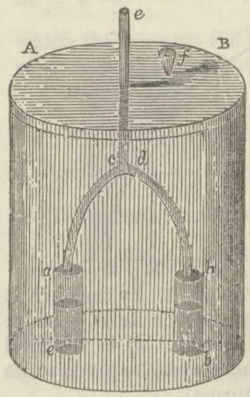
A moveable branch syphon, in which there is a joint at the top D, is a most valuable instrument, and the idea of it was first given by the late Mr Bryce, who employed it in place of a stomach-pump, in order to throw fluids into the stomach, or to extract them from it. The two branches may be made of metal, glass, or any other substance, the two parts being united by an air-tight joint. In cases of exigency two glass tubes, or pieces of any tube, might be joined into a syphon, by making the joint of a piece of bladder. One of the branches may be raised into any position for the purpose of charging it, and the instrument may be hung up charged, and ready for use, by a ring at the extremity of each branch.

71. In order to shew that the effect of the syphon depends upon the gravitation of fluids, M. Pascal devised the following experiment: In the large glass vessel AB, fasten by means of bees-wax two cylindrical cups a, b, containing tinged water, whose surface is about an inch higher in the one than in the other. Into the tinged water insert the legs of a glass syphon cd, having an open tube e fixed into the middle of it, and put a wooden cover on the vessel with a hole in its centre to receive the tube, and keep it in a vertical position. Then through the funnel f, fixed in another part of the cover, pour oil of turpentine into the larger vessel till it flow into the cups a, b, and rise above the arch of the syphon. The pressure of the oil upon the tinged water in the cups will cause the water to pass through the syphon from the higher cup to the lower, till the surfaces of the water in both the cups be reduced to a level. In order to explain this, suppose a horizontal plane eb to pass through the legs of the syphon, and the tinged water in the cups, the parts of this plane within the legs when the syphon is full, will be equally pressed by the columns of tinged water ce, db within the syphon; but the equal parts of this plane between the circumference of each leg of the syphon, and the circumference of each cylindrical cup, their diameters being equal, will sustain unequal pressures from their superincumbent columns, though the altitudes of these columns be equal. For since the pressure upon e is exerted by a column of oil ac, and a column of water ae, whereas the pressure upon b is exerted by a column of oil hd, and a column of water hb; the column ce, which contains the greatest quantity of water, will evidently exert the greatest force, and by its pressure will drive the tinged water from the cup a, through the syphon acd into the cup b, until a perfect equilibrium is obtained by an equality between the columns of water ae and hb.

Pressure, &c. of Fluids.

Experiment shewing that the effect of the syphon depends on the gravitation of fluids.

Fig. 19.



Sect. III.—*Application of the Principles of Hydrostatics to the Construction of Dikes, &c. for resisting the Pressure of Water.*

Definition.

Definition.

A dike is an obstacle either natural or artificial, which opposes itself to the constant effort of water to spread itself in every direction.

Different ways in which a dike may yield to the pressure of water.

72. In discussing this important branch of hydraulic architecture, we must inquire into the thickness and form which must be given to the dike in order to resist the pressure of the water. In this inquiry the dike may be considered as a solid body, which the water tends to overthrow, by turning it round upon its posterior angle C; or it may be regarded as a solid, whose foundation is immoveable, but which does not resist the pressure of the water through the whole of its height, and which may be separated into horizontal sections by the efforts of the fluid. A dike may considered also as a solid body which can be neither broken nor overturned, but which may be pushed horizontally from its base, and can preserve its stability only by the friction of its base on the ground which supports it. On these conditions are founded the calculations in the following proposition which contain the most useful information that theory can suggest upon the construction of dikes.

Prop. I.

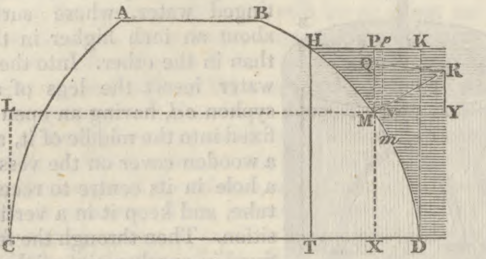
73. To find the dimensions of a dike which the water tends to overthrow by turning it round its posterior angle.

Pressure, &c. of Fluids.

To find the dimensions of a dike when water tends to turn it round its posterior angle.

Let ABCD, fig. 20, be the section of the dike, considered as a continuous solid, or a piece of firm masonry, HK the level

Fig. 20.



of the water which tends to overthrow it, by turning it round its posterior angle C, supposed to be fixed, and let AC, BD, be right lines or known curves. It is required to determine CD, the thickness which must be given to its base to prevent it from being overturned.

To the surface of the water HK draw the ordinates PM, pm infinitely near each other, and let fall from the points H and M the perpendiculars HT, MX. Draw the horizontal line ML and raise the perpendicular CL, and suppose

HP	$= x$
PM	$= y$
Pp or MV the fluxion of x	$= \dot{x}$
Vm the fluxion of y	$= \dot{y}$
HT	$= a$
DT	$= b$
CD	$= z$
The momentum of the area ABCD, or the force with which it resists being turned round the fulcrum C	$= Z$
The specific gravity of water	$= s$
The specific gravity of the dike	$= \sigma$

74. It is obvious, from art. 57, that every element sustains a perpendicular pressure proportional to the height PM. Let RM perpendicular to Mm represent the force exerted by the column of water MmpP, and let it be decomposed into two other forces, one of which RQ is horizontal, and has a tendency to turn the dike round the point C, and the other RY is vertical, and tends to press the dike upon its base. The force RQ is evidently $= s \times y \times \overline{\mathrm{M}m}$ (58.), and therefore the horizontal part of it will be only $sy \times \mathrm{M}m \times \frac{\mathrm{RQ}}{\mathrm{RM}}$. But the triangles RQM, MVm are evidently similar, consequently RQ:RM=Vm:Mm; hence $\frac{\mathrm{RQ}}{\mathrm{RM}} = \frac{\mathrm{V}m}{\mathrm{M}m} = \frac{\dot{y}}{\mathrm{M}m}$. Wherefore by substitution we have the force $\mathrm{RQ} = sy \times \mathrm{M}m \times \frac{\dot{y}}{\mathrm{M}m}$, and dividing by M$m$, we have $\mathrm{RQ} = sy\dot{y}$. The force RQ, therefore, will always be the same as the force against Vm, whatever be the nature of the curve BD. Now the momentum of this force with relation to the fulcrum C, or its power to make the dike revolve round C, is measured by the perpendicular CL, let fall from the centre of motion to the direction in which the force is exerted (see MECHANICS), consequently this momentum will be $sy\dot{y} \times \mathrm{CL} = sy\dot{y} \times \overline{a - y}$ (since $\mathrm{CL} = \mathrm{HT} - \mathrm{PM} = a - y$) $= say\dot{y} - syy\dot{y}$, whose fluent is $\frac{sayy}{2} - \frac{sy^3}{3}$, which by supposing $y = a$ becomes $\frac{1}{6} sa^3$ for the total momentum of the horizontal effort of the water to turn the dike round C. The vertical force RY or QM, which presses the dike upon its base. is evidently $sy \times \mathrm{M}m \times \frac{\mathrm{MQ}}{\mathrm{RM}}$, but on account of the similar triangles, $\frac{\mathrm{MQ}}{\mathrm{RM}} = \frac{\dot{x}}{\mathrm{M}m}$, consequently by substitution we shall have the force $\mathrm{RY} = sy \times \mathrm{M}m \times \frac{\dot{x}}{\mathrm{M}m} = sy\dot{x}$, after division by M$m$. The momentum, therefore, of the vertical force RY with relation to C, or its power to prevent the dike from moving round the fulcrum C, will be $sy\dot{x} \times \mathrm{CX}$; CX being the arm of the lever by which it acts, or the perpendicular let fall from the fulcrum upon the direction of the force. Now $\mathrm{CX} = \mathrm{CD} - \mathrm{DT} + \mathrm{TX}$ or HP, that is $\mathrm{CX} = \overline{z - b + x}$, therefore the momentum of the force $\mathrm{RY} = sy\dot{x} \times \overline{z - b + x}$, and the sum of the similar momenta from F to H will be the fluent $\int (\overline{z - b + x})\, sy\dot{x}$, the combined momentum of all the vertical forces which resist the efforts of the horizontal forces to turn the dike round C. But the efforts of the horizontal forces are also resisted by the weight of the dike, whose momentum we have called Z, therefore σZ, σ being the specific gravity of the dike, will be the momentum of the dike. We have now three forces acting at once, viz. the horizontal force of the water striving to overturn the dike, and the vertical force of the water combined with the momentum of the dike, striving to resist its overthrow, therefore we shall have an equilibrium between these three forces, when the momentum of the horizontal forces is made equal to the momentum of the vertical forces, added to that of the dike itself, consequently

$$\tfrac{1}{6} sa^3 = \int (z - b + x)\; sy\dot{x} + \sigma \mathrm{Z}.$$

75. As it is necessary, however, to give more stability to the dike than what is just requisite to preserve its equilibrium, we must make its dimensions such as to resist a force greater than the horizontal forces, a force, for example, n times the momentum of the horizontal forces.[1] The equation will therefore become

$$\text{(I.)}\quad n \times \tfrac{1}{6}\, sa^3 = \int (z - b + x)\, sy\dot{x} + \sigma \mathrm{Z},$$

which comprehends every possible case of stability; for if we wish the stability of the dike to have double the stability of equilibrium, we have only to make $n = 2$. The preceding general equation is susceptible of a variety of applications according to the nature of the curves which form the sides of the dike. It is at present worthy of remark, that since the momentum of the horizontal forces is always the same, whatever be the curvature of the sides AC, BD, and since the momentum of the vertical forces increases as the angle CDH diminishes, it follows that it will always be advantageous to diminish the angle CDH, and give as much slope as possible to the sides of the dike.

Equation containing the conditions of equilibrium on the supposition that the dike may slide upon its base.

76. Let us now consider the conditions that may be necessary to prevent the dike ABCD from sliding on its base CD. Since the base of the dike is supposed horizontal, the force which the dike opposes to the horizontal efforts of the water arises solely from the adhesion of the dike to its base, and from the resistance of friction. These two forces, there-

[1] The dimensions of the dike would be sufficiently strong to resist any additional force by neglecting the term σZ, which represents the vertical pressure of the water tending to keep the dike upon its base.

Pressure, &c. of Fluids.

fore, combined with the weight of the dike, form the force which resists the horizontal efforts of the water; an equilibrium will consequently obtain when the three first forces are made equal to the last. But the force of adhesion, and the resistance of friction, being unknown, may be made equal to the weight of the dike multiplied by the constant quantity m, which must be determined by experience. Now, calling A the area of the section ABCD, we shall have σA for its weight, and $m\sigma A$ for the resistance which is opposed to the horizontal efforts of the water. But we have already seen that the horizontal forces of the water upon M are equal to $sy\dot{y}$, whose fluent $\frac{1}{2}sa^2$ (when $a=y$) is the sum of all the horizontal forces; consequently, when an equilibrium takes place between these opposing forces, we shall have,

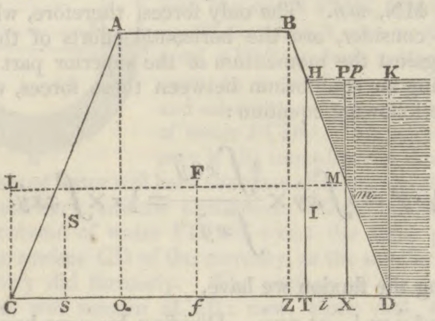
$$\text{(II.)}\ m\sigma A=\tfrac{1}{2}sa^2,\ \text{or}\ A=\frac{s}{\sigma}\times\frac{a^2}{2m}.$$

We might have added to the weight of the dike the vertical pressure of the water, but it has been neglected for the purpose of having the dike sufficiently strong to resist an additional force.

Form of the general equation when the sides of the dike are rectilineal.

77. We shall now proceed to inquire into the form which the general equation assumes when the sides of the dike are rectilineal. Let AC, BD, fig. 21. be two lines inclined to the horizon under given angles ACD, BDC, and let AB, CD be two horizontal lines. Retaining the construction and symbols in art. 73, let fall AQ, BZ, perpendicular to CD, and make $AQ=BZ=d$, $CQ=r$, and $DZ=r'$.

Fig. 21.



On account of the similar triangles HPM, FTH we shall have $a:b=y:x$, and therefore $x=\frac{by}{a}$. Substituting this value of x, instead of x in the general equation, art. 75, we have $\int(z-b+x)\ sy\dot{x}=\int\frac{sb}{a}\left(z-b+\frac{by}{a}\right)\ y\dot{y}=\frac{sbzyy}{2a}-\frac{sbbyy}{2a}+\frac{sbby^3}{3a^2}=(\text{making } y=a)\ \frac{sbza}{2}-\frac{sb^2a}{6}$; now the momentum of the dike ABCD with relation to C, is equal to the whole area of the dike ABCD collected in its centre of gravity, and placed at the end of a lever whose length is the horizontal distance of that centre of gravity from the fulcrum C. But the area of $ABQZ=QZ\times ZB=\overline{z-r'-r}\times d$; the area of the triangle $ACQ=\frac{CQ\times QA}{2}=\frac{dr}{2}$, and the area of the triangle $BZD=\frac{DZ\times ZB}{2}=\frac{dr'}{2}$. Now the lever by which the area ABQZ, collected in its centre of gravity F. acts upon the fulcrum, is evidently $=Cf=CQ+Qf=CQ+\frac{1}{2}QZ=r+\frac{\overline{z-r'-r}}{2}$, consequently the momentum by which the area ABCD resists the horizontal forces that conspire to give it a motion of rotation about C will be $=\overline{z-r'-r}\times d\times r+\frac{\overline{z-r'-r}}{2}$. The lever by which the triangle BZD acts, when collected in its centre of gravity I, is evidently Ci; but by the property of the centre of gravity $Di=\frac{2}{3}DZ=\frac{2r'}{3}$, hence $Ci=CD-Di=z-\frac{2r'}{3}$, consequently the energy of the triangle BZD to resist the efforts of the water acting horizontally will be $=\frac{dr'}{2}\times\overline{z-\frac{2r'}{3}}$. The lever of the triangle ACQ is plainly $Cs=\frac{2}{3}CQ=\frac{2r}{3}$, consequently the momentum of ACQ, collected in its centre of gravity S, will be $=\frac{dr}{2}\times\frac{2r}{3}$. Having thus found the momentum of the rectangle ABQZ, and of the triangles BZD, ACQ, the sum of these momenta will be the momentum Z, with which the dike opposes the horizontal efforts of the water, therefore we shall have

$$Z=\overline{z-r'-r}\times d\times r+\frac{\overline{z-r'-r}}{2}+\frac{dr'}{2}\times\overline{z-\frac{2r'}{3}}+\frac{dr}{2}\times\frac{2r}{3};$$

and by multiplication,

$$Z=\frac{dzz}{2}-\frac{dr'z}{2}+\frac{dr'r'}{6}-\frac{drr}{6}.$$

By substituting this value of Z in the general equation in art. 75, we shall have

Resulting equation when both its sides are rectilineal and inclined.

$$\text{(III.)}\ n\times\tfrac{1}{6}sa^3=\frac{sbza}{2}-\frac{sbba}{6}+\frac{\sigma dzz}{2}-\frac{\sigma dr'z}{2}+\frac{\sigma dr'r'}{6}-\frac{\sigma drr}{6}.$$

a quadratic equation, which will determine in general the base z of a dike, when its sides are rectilineal and inclined at any angle to the horizon.

78. When the angle ACQ is a right angle, or when the posterior side AC of the dike is perpendicular to the horizon, the quantity r becomes $=0$, and the last term of the preceding equation in which r appears will vanish, consequently the equation will now become

Resulting equation when the posterior side of the dike is vertical.

$$\text{(IV.)}\ n\times\tfrac{1}{6}sa^3=\frac{sbza}{2}-\frac{sbba}{6}+\frac{\sigma dzz}{2}-\frac{\sigma dr'z}{2}+\frac{\sigma dr'r'}{6}.$$

Resulting equation when both sides of the dike are vertical.

79. When the angles ACQ and BDZ are both right, the dike becomes rectangular, with its sides perpendicular to its base. In this case both r and r' become each $=0$, and therefore all the terms in which they are found will vanish. In this case too $DT=b$ becomes $=0$, and therefore the terms in which it appears will likewise vanish. The general equation will now become

$$\text{(V.)}\ n\times\tfrac{1}{6}sa^3=\frac{\sigma dzz}{2}\ \text{a pure quadratic.}$$

Application of the formulæ.

80. In order to shew the application of the preceding formulæ, and at the same time the advantage of inclining the sides of the dike, let us suppose the depth of the water, and also the height of the dike, to be 18 feet, so that B will coincide with H. Let us also suppose, what is generally the case in practice, that the declivity of the sides is $\frac{1}{6}$ of

Pressure, &c. of Fluids.

their altitude, that is $DZ = CQ = \frac{1}{6} BZ$. Let the specific gravity of the dike be to that of water as 12 to 7; and suppose it is wished to make the stability of the dike twice as great as the stability of equilibrium, that is, to make it capable of resisting a force twice as great as that which it really sustains. Then, upon these conditions, we shall have $BZ = HT$, or $a = d = 18$ feet; $CQ = DZ = DT$, or $r' = r = b = 3$ feet; $s = 7$; $\sigma = 12$; and $n = 2$. By substituting these numerical values in the general equation No. III, it becomes

$$zz - \frac{45}{36} z = \frac{4599}{39} \text{ feet};$$

a quadratic equation, which, after reduction, will give $z = 12$ feet nearly. When $z = 12$, the area of the dike ABCD will be 162 square feet.

Advantages of inclining the sides of the dike.

81. Let us now suppose the sides of the dike to be vertical, the equation No. V. will give us $z = 11$ feet 2 inches, which makes the area of the dike more than 201 square feet. The area of the dike with inclined sides is therefore to its area with vertical sides nearly as 4 to 5: and hence we may conclude that a dike with inclined sides has the same stability as a dike with vertical sides, while it requires $\frac{1}{5}$ less materials.

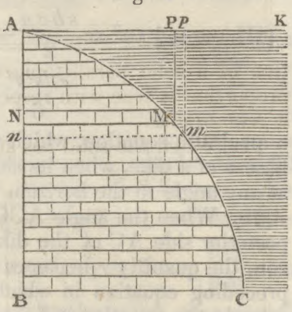
Prop. II.

82. To find the dimensions of a dike which can neither slide upon its base, nor turn round its posterior angle; but which is composed of horizontal sections, which may be separated from each other.

To find the dimensions of the dike when water tends to separate it into horizontal sections.

In solving this proposition, we must find the curvature of the side exposed to the pressure of the water, which will make all the different sections or horizontal laminæ equally capable of resisting the different forces which tend to separate them. If the lamina NM does not resist the column PM, which partly presses it in the direction MN as powerfully as the lamina nm resists the horizontal pressure of the column pm, the lamina NM is in danger of being separated from the lamina nm. But if all the laminæ NM, nm resist with equal force the horizontal efforts of the water, and if the dike cannot be made to slide upon its base nor turn round its posterior angle T, it cannot possibly yield to the pressure of the water; for it is impossible to separate one lamina from another, unless the one opposes a less resistance than the other. To simplify the investigation as much as possible, let us suppose the posterior side of the dike to be vertical, and the depth of the water to be equal to the height of the dike.

Fig. 22.



83. Let ABC be the section of the dike, AK the surface of the water, AC the curvature required, AB its posterior side; MN nm a horizontal lamina infinitely small, in the direction of which the dike has a tendency to break, in consequence of the efforts of the water upon AM.

If the dike should break in the direction MN, the superior part AMN will detach itself from the inferior part MNBC, by moving from M towards N; and at the moment when the impulse takes place, it will have a small motion of rotation round the point N. We must therefore determine the forces which act upon the lamina MNnm, and form an equation expressing their equilibrium round the point N. The forces alluded to are evidently, 1. The horizontal efforts of the water; 2. The vertical efforts of the water; 3. The weight of the part AMN; and, 4. The adhesion of the two surfaces MN, mn. Of these four forces, the first is the only one which has a tendency to overthrow the portion AMN of the dike; and its efforts are resisted by the three other forces. In order to find the momenta of these forces with regard to the point N, let us suppose

Enumeration of the forces which act upon the dike.

$$\begin{array}{ll} AP = NM & = x \\ PM & = y \\ \text{The specific gravity of water} & = s \\ \text{The specific gravity of the dike} & = \sigma \end{array}$$

Then we shall have,

Momentum of these forces.

1. The momentum of the horizontal forces of the water will be $= \frac{1}{6} sy^3$, by the same reasoning that was employed in art. 74.

2. The momentum of the part AMN of the dike will be $= \sigma \int x\dot{y}$ the area of the surface AMN, multiplied by the distance of its centre of gravity from the fulcrum N, which is equal to $\dfrac{\frac{1}{2}\int xx\dot{y}}{\int x\dot{y}}$. See Mechanics.

84. In order to simplify the calculus, and at the same time increase the stability of the dike, we shall neglect the vertical force of the water, and the adhesion of the two surfaces MN, mn. The only forces, therefore, which we have to consider, are the horizontal efforts of the water acting against the momentum of the superior part AMN. By making an equilibrium between these forces, we shall have the following equation:

$$\tfrac{1}{2} sy^3 = \sigma \int x\dot{y} \times \frac{\frac{1}{2}\int xx\dot{y}}{\int x\dot{y}} = \tfrac{1}{2}\sigma \times \int xx\dot{y}.$$

By taking the fluxion we have,

$\frac{1}{2} sy^2 \dot{y} = \frac{1}{2} \sigma \times xx\dot{y}$. Dividing by $\dot{y}$ we have

$\frac{1}{2} sy^2 = \frac{1}{2} \sigma \times x^2$, which by reduction becomes

$$y = \sqrt{\frac{\sigma}{s}} \times x.$$

The line AMC therefore is rectilineal, and the base BC is to the altitude BA as $\sqrt{s} : \sqrt{\sigma}$; that is, as the square root of the specific gravity of the water is to the square root of the specific gravity of the dike.

Equation containing the conditions of equilibrium on the supposition that the dike may slide upon its base.

85. In order to prevent the superior portion AMN from sliding on its base MN, we must procure an equilibrium between the adhesion of the surfaces MN, mn and the horizontal force exerted by the water. Now, the sum of all the horizontal forces exerted by the water is (by art. 76.) $\frac{1}{2} sy^2$, and the adhesion may be represented by some multiple m, of its weight, the constant quantity m being determined by experience. The adhesion will therefore be $m \times \sigma \int x\dot{y}$, and the equation of equilibrium will be

$\frac{1}{2} sy^2 = m \times \sigma \int x\dot{y}$, the fluxion of which is

$sy\dot{y} = m \times \sigma x\dot{y}$. Dividing by $\dot{y}$ we have

$sy = m\sigma x$, and therefore

$x : y = s : m\sigma$.

Hence the base BC of the dike is to its altitude BA as the specific gravity of water is to a multiple m of the specific

Of Specific Gravities.

gravity of the dike, m being a constant quantity which experiments alone can determine.

In a work by the Abbé Bossut and M. Viallet, entitled *Recherches sur la Construction la plus avantageuse des Digues*, the reader will find a general solution of the preceding problem, in which the vertical efforts of the water and the adhesion of the surfaces are considered. This able work, which we have followed in the preceding investigation, contains much practical information on the construction of dikes of every kind; and may be considered as a continuation of the second part of Belidor's *Architecture Hydraulique*.

CHAPTER II.—OF SPECIFIC GRAVITIES.

Definition.

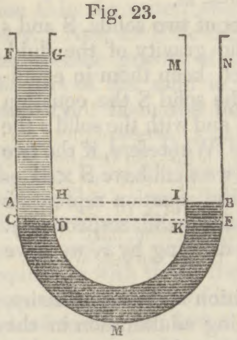
Specific gravity defined.

86. The absolute weights of different bodies of the same bulk are called their *specific gravities* or *densities;* and one body is said to be *specifically heavier* or *specifically lighter* than another, when under the same bulk it contains a greater or less quantity of matter. Brass, for example, is said to have eight times the specific gravity of water, because one cubic inch of brass contains eight times the quantity of matter, or is eight times heavier than a cubic inch of water.

Prop. I.

87. Fluids pressing against each other in two or more communicating vessels, will be in equilibrio when the perpendicular altitudes above the level of their junction are in the inverse ratio of their specific gravities.

Fig. 23.



If a quantity of mercury be poured into the vessel FMN, it will be in equilibrio when it rises to the same level AHIB, in both tubes. Take away an inch of mercury ACDH, and substitute in its room $13\frac{1}{2}$ inches of water FCDG. Then since mercury is $13\frac{1}{2}$ times heavier than water, $13\frac{1}{2}$ inches of water will have the same absolute weight as one inch of mercury, and the equilibrium will not be disturbed; for the column of water FD will exert the same pressure upon the surface CD of the mercury, as the smaller column of mercury did formerly. The surface of the mercury, therefore, will remain at IB: now, since AB, CE, are horizontal lines, AC will be equal to IK; but FC was made $13\frac{1}{2}$ times AC, therefore $FC = 13\frac{1}{2}$ times IK, that is $FC : IK = 13\frac{1}{2} : 1$, the ratio between the specific gravities of mercury and water.

Construction of the barometer.

88. On this proposition depends the theory of the barometer. Let a quantity of mercury be introduced into the tube FMN, and let the pressure of the atmosphere be removed from the surface IB; the pressure of the air upon the other surface CD will be the same as if the tube FD were continued to the top of the atmosphere, and therefore, instead of the column of water FD we have a column of air equal to the height of the atmosphere acting against the mercury CDMIB; the mercury consequently will rise towards N, so that its height will be to the height of the atmosphere as the specific gravity of air is to the specific gravity of mercury; but as the density of the air diminishes as it recedes from the earth, we must take the specific gravity of the air at a mean height in the atmosphere. It is obvious from the proposition, that the altitude of the column of mercury which balances the column of air, must be reckoned from CD, the level of their junction; and that, when the specific gravity of the air is diminished, the mercury will fall, and will again rise when it regains its former density.

Prop. II.

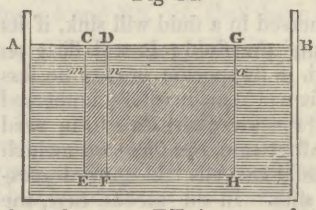
Bodies immersed in a fluid are pressed upwards with a force equal to the weight of the quantity of fluid displaced.

89. If any body is immersed in a fluid, or floats on its surface, it is pressed upwards with a force equal to the weight of the quantity of fluid displaced.

Demonstration when a parallelopiped is immersed in the fluid.

Let mH be the section of a body immersed in the vessel AB filled with a fluid. Any portion mn of its upper surface is pressed downwards by the column of fluid CmnD (59.); but the similar portion EF of its lower surface is pressed upwards with a column of fluid equal to CEFD, therefore the part EF is pressed upwards with the difference of these forces, that is, with a force equivalent to the column of fluid mEFn, for CEFD — CmnD = mEFn. In the same way it may be shewn, that the remaining part FH is pressed upwards with a force equal to the weight of a column nFHo; and therefore it follows, that the rectangle mEHo is pressed upwards with a force equivalent to a column mEHo, that is, to the quantity of fluid displaced.

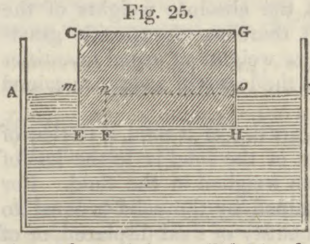
Fig. 24.



When the parallelopiped floats in the fluid.

90. If the body floats in the fluid, like CH in the vessel AB, the same consequence will follow; for the body CH is evidently pressed upwards with a force equivalent to the column mEHo, that is, to the part immersed or the quantity of fluid displaced. Now, as the same may be demonstrated of every other section of a solid parallelopiped, we may conclude, that the proportion is true with respect to every solid whose section is rectangular.

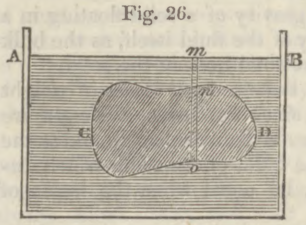
Fig. 25.



When the solid has any other form.

91. When the solid has any other form, as CD, however irregular, we may conceive its section to be divided into a number of very small rectangles $n\,o$: then (57.) the small portion of the solid at n is pressed downwards by a column of particles $m\,n$, and the small portion at o is pressed upwards by a column of particles equal to $n\,o$; therefore the difference of these forces, viz. the column $n\,o$, is the force with which the portion o is pressed upwards. In the same manner it can be shewn, that every other similar portion of the lower surface of the solid CD is pressed upwards with a force equal to a column of particles whose height is equal to the vertical breadth of the solid; but all these columns of particles must occupy the same space as the solid itself, therefore any solid body immersed in a fluid, or floating on its surface, is pressed upwards with a force equal to the weight of the quantity of fluid displaced.

Fig. 26.



The weight of a floating body is equal to the weight of the quantity of fluid displaced.

92. Cor. 1. When a body floats in a fluid, the weight of the quantity of fluid displaced is equal to the weight of the floating solid. For since the solid is in equilibrium with the fluid, the force which causes it to descend must be equal to the force which presses it upwards; but the force which keeps a part of the solid immerged in the fluid is the weight of the solid, and the force which presses the solid upwards, and prevents it from sinking, is equivalent to the weight of the quantity of fluid displaced (89.); there-

Of Specific Gravities.

fore these forces, and the weights to which they are equivalent, must be equal.

93. Cor. 2. A solid weighed in a fluid loses as much of its weight as is equal to the weight of the quantity of fluid displaced; for since the body is pressed upwards with a force equal to the weight of the fluid displaced (89.), this pressure acts in direct opposition to the natural gravity or absolute weight of the solid, and therefore diminishes its absolute weight by a quantity equal to the weight of the fluid displaced. The part of the weight thus lost is not destroyed: It is only sustained by a force acting in a contrary direction.

94. Cor. 3. A solid immersed in a fluid will sink, if its specific gravity exceed that of the fluid: It will float on the surface, partly immersed, if its specific gravity be less than that of the fluid; and it will remain wholly immersed wherever it is placed, if the specific gravities of the solid and fluid are equal. In the first case, the force with which the solid is pressed downwardly exceeds the upward pressure, and therefore it must sink. In the second case, the upward pressure exceeds the pressure downwards, and therefore the body must float; and, in the third case, the upward and downward pressures being equal, the solid will remain wherever it is placed.

95. Cor. 4. The specific gravities of two or more fluids are to one another as the losses of weight sustained by the same solid body, and specifically heavier than the fluids, when weighed in each fluid respectively. The solid in this case displaces equal quantities of each fluid; but the losses of weight are respectively as the absolute weights of the quantities displaced (Cor. 2.), therefore the specific gravities, which are as the absolute weights of equal quantities of any body (86.), must be as the losses of weight sustained by the immersed solid.

96. Cor. 5. The specific gravity of a solid is to that of a fluid as the absolute weight of the solid is to the loss of weight which it sustains when weighed in the fluid. For since the loss of weight sustained by the solid is equal to the absolute weight of the quantity of fluid displaced, or of a quantity of fluid of the same bulk as the solid, the specific gravities, which (86.) are in the ratio of the absolute weights of equal volumes, must be as the absolute weight of the solid to the loss of weight which it sustains.

97. Cor. 6. The specific gravity of a solid floating in a fluid, is to the specific gravity of the fluid itself, as the bulk of the part immersed is to the total bulk of the solid.

98. Cor. 7. Bodies which sustain equal losses of weight are of the same bulk. For, since the losses of weight are as the weights of the quantities of fluid displaced, and as the quantities displaced are as the bulks of the solids which displace them, the bulks must be equal when the losses of weight are equal.

The preceding corollaries deduced from an equation of equilibrium.

99. The preceding corollaries may be expressed algebraically, and may be deduced from a general equation in the following manner. Let B be the total bulk of a floating body, and C the part of it which is immersed; let S be the specific gravity of the solid, and s that of the fluid. Then it is obvious, that the absolute weight of the solid will be expressed by $B \times S$, and the absolute weight of the fluid displaced by $C \times s$; for the fluid displaced has the same bulk as the part of the solid which is immersed. In order that an equilibrium may obtain between the solid and fluid, we must have $B \times S = C \times s$: Now, when $s > S$, we have $B > C$, so that the solid will float, which is the second case of Cor. 3.—When $S = s$ we have $B = C$, which is the third case of Cor. 3.—When $S > s$ we have $C > B$, that is, the body will sink below the surface; and it will descend to the bottom, for it cannot be suspended in the fluid without some power to support it; and if such a power were necessary, we should have $B \times S > C \times s$, which is contrary to the equation of equilibrium.

100. From the equation $B \times S = C \times s$ we have (Euclid VI. 16.) $S : s = B : C$, which is Cor. 6.—When the body is completely immersed we have $B = C$, in which case the equation becomes $B \times S = B \times s$; and when the solid is specifically heavier than the fluid, it will require a counterweight to keep the solid suspended in the fluid. Let W be the counterweight necessary for keeping the solid suspended in the fluid, then in the case of an equilibrium the equation will be $B \times s + W = B \times S$, or $B \times S - W = B \times s$, or $S \times \overline{B \times S - W} = S \times B \times s$, whence (Euclid VI. 16.) $S : s = B \times S : B \times S - W$, which is Cor. 5.

101. If the same solid body is plunged in a second fluid of a different specific gravity from the first, let σ be the specific gravity of the second fluid, and w the counterweight necessary to keep the solid suspended in it.—The equation for the first fluid was $B \times s + W = B \times S$ (100.), and the equation for the second fluid will be $B \times \sigma + w = B \times S$; therefore we shall have, by the first equation, $S \times B - W = s \times B$, and by the second $S \times B - w = \sigma \times B$, and consequently $s \times B : \sigma \times B = S \times B - W : S \times B - w$, or (Euclid V. 16.) $s : \sigma = S \times B - W : S \times B - w$, which is Cor. 4.; for the losses of weight in each fluid are evidently represented by $\overline{S \times B} - W$ and $\overline{S \times B} - w$.

102. If B and b express the bulks of two solids, S and s their specific gravities, σ the specific gravity of the fluid, and W, w the counterweights which keep them in equilibrium with the fluid. Then with the solid S the equation will be $S \times B - W = \sigma \times B$ (101.); and with the solid s the equation will be $s \times b - w = \sigma \times b$. Wherefore, if the two solids sustain equal losses of weight, we shall have $S \times B - W = s \times b - w$, since each side of the equation represents the loss of weight sustained by each solid respectively. Consequently, $\sigma \times B = \sigma \times b$, and dividing by σ, we have $B = b$, which is Corollary 7.

Method of detecting adulteration in metals.

103. From the preceding proposition and its corollaries, we may deduce a method of detecting adulteration in the precious metals, and of resolving the problem proposed to Archimedes, by Hiero, king of Syracuse. Take a real guinea, and a counterfeit one made of copper and gold. If the latter be lighter than the former, when weighed in a pair of scales, the imposition is instantly detected; but should their weight be the same, let the two coins be weighed in water, and let the loss of weight sustained by each be carefully observed, it will then be found that the counterfeit will lose more of its weight than the unadulterated coin. For, since the specific gravity of copper exceeds that of gold, and since the absolute weights of the coins were equal, the counterfeit guinea must be greater in bulk than the real one, and will therefore displace a greater quantity of water, that is (93.), it will lose a greater part of its weight.

Problem proposed by Hiero to Archimedes.

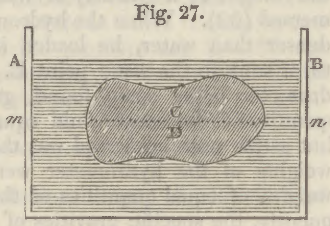
104. Hiero, king of Syracuse, having employed a goldsmith to make him a crown of gold, suspected that the metal had been adulterated, and inquired at Archimedes if his suspicions could be verified or disproved without injuring the crown. The particular method by which Archimedes detected the fraud of the goldsmith is not certainly known; but it is probable that he did it in the following manner. A quantity of gold, of the same absolute weight as the crown, would evidently have the same bulk also, if the crown were pure gold, and would have a greater bulk if the crown were made of adulterated gold. By weighing, therefore, the quantity of gold and the crown in water, and observing their respective losses of weight, Archimedes found that the crown lost more of its weight than the quantity of gold; and therefore concluded, that as the crown must have displaced a greater portion of water than the piece of gold, its bulk must likewise have been greater, and the metal adulterated of which it was composed.

Specific Gravities.

Prop. III.

105. If two immiscible fluids, of different specific gravities, and a solid of an intermediate specific gravity, be put into a vessel, the part of the solid in the lighter fluid will be to the whole solid, as the difference between the specific gravities of the solid and the heavier fluid, is to the difference between the specific gravities of the two fluids.

Fig. 27.



Let AB (fig. 27.) be the vessel which contains the two fluids, suppose mercury and water, and the solid CD. The mercury being heavier than water, will sink to the bottom, and have mn for its surface, and the water will occupy the space AB mn. The solid having a greater specific gravity than water, will sink in the water (94.); but having a less specific gravity than mercury, it will float in the mercury. It will therefore be suspended in the fluids, having one portion C in the water, and the other portion D in the mercury. Now let S be the specific gravity of the mercury, s the specific gravity of the water, σ that of the solid, C the part of the solid in the water, and D the part in the mercury. Then the bulk of the solid is $C+D$, and its weight $\sigma \times \overline{C+D}$: The quantity of water displaced by the part C, or the loss of weight sustained by the part C, will be $C \times s$; and the quantity of mercury displaced, or the loss of weight sustained by part D, will be $D \times S$. But as the solid is suspended in the fluids, and therefore in equilibrio with them, the whole of its weight is lost. Consequently, the part of its weight which is lost in the water, added to the part lost in the mercury, must be equal to its whole weight; that is, $\overline{C \times s} + \overline{D \times S} = \sigma \times \overline{C+D}$, or $s\,C + SD = \sigma\,C + \sigma\,D$. Transposing $\sigma\,C$ and SD, we have $s\,C - \sigma\,C = SD - \sigma\,D$, or $C \times \overline{s - \sigma} = D \times \overline{S - \sigma}$, and (Euclid VI. 16.) $C : D = \overline{s - \sigma} : \overline{S - \sigma}$. Then, by inversion and composition (Euclid V. Propositions B and 18.) $C : \overline{C+D} = \overline{S - \sigma} : \overline{S - s}$. Q. E. D.

106. Cor. 1. From the analogy $C : D = \overline{s - \sigma} : \overline{S - \sigma}$, we learn that the part of the solid in the heavier fluid, is to the part in the lighter fluid, as the difference between the specific gravities of the solid and the lighter fluid, is to the difference between the specific gravities of the solid and the heavier fluid.

107. Cor. 2. When s is very small compared with S, we may use the analogy $C : C+D = \sigma : s$, though in cases where great accuracy is necessary this ought not to be done. When the specific gravity of a body, lighter than water, is determined by comparing the part immersed with the whole body, there is evidently a small error in the result; for the body is suspended partly in water and partly in air. It is, in fact, a solid of an intermediate specific gravity floating in two immisceable fluids, and therefore its specific gravity should be ascertained by the present proposition.

Prop. IV.

108. If two bodies, whether solid or fluid, be mixed together so as to form a compound substance, the bulk of the heavier is to the bulk of the lighter ingredient, as the difference between the specific gravities of the compound, and the lighter ingredient, is to the difference between the specific gravities of the compound and the heavier ingredient.

Of Specific Gravities.

To find the bulk of the ingredients, their specific gravities and that of the compound being given.

Let S and s be the specific gravities of the two ingredients, σ the specific gravity of the compound, and B, b the bulks of the ingredients; then the bulk of the compound will be $B+b$, and its weight $\sigma \times \overline{B+b}$. The weight of the ingredient B will be $B \times S$, and that of the other ingredient $b \times s$; and as the weight of the compound must be equal to the weight of its ingredients, we have the following equation $\sigma\,b + \sigma\,B = BS + b\,s$, and by transposing $\sigma\,b$ and BS, we shall have $B\,\sigma - BS = b\,s - b\,\sigma$, or $B \times \overline{\sigma - S} = b \times \overline{s - \sigma}$; therefore (Euclid VI. 16.) $B : b = \overline{s - \sigma} : \overline{\sigma - S}$. Q. E. D.

A compound mass, whether solid or fluid, is sometimes greater in bulk than the sum of the bulks of its ingredients.

109. In the preceding proposition, it has been taken for granted that the magnitude of the compound is exactly equal to the sum of the magnitudes of the two ingredients. This, however, does not obtain universally either in fluids or solids; for an increase or diminution of bulk often attends the combination of two different ingredients. A cubical inch of alcohol, for example, combined with a cubical inch of water, will form a compound which will measure less than two cubical inches; and a cubical inch of tin, when incorporated in a fluid state with a cubical inch of lead, will form a compound, whose bulk will exceed two cubical inches. The preceding proposition, however, is, even in these cases, of great use in ascertaining the increase or decrease of bulk sustained by the compound, by comparing the computed with the observed bulk.

Prop. V. Problem.

110. How to determine the specific gravities of bodies, whether solid or fluid.

To determine the specific gravities of solids and fluids.

The simplest and most natural way of finding the specific gravities of bodies would be to take the absolute weights of a cubic inch, or any other determinate quantity, of each substance; and the number thus found would be their specific gravities. But as it is difficult to form two bodies of the very same size, and often impossible, as in the case of precious stones, to give a determinate form to the substance under examination, we are obliged to weigh them in a fluid, and deduce their specific gravities from the losses of weight which they severally sustain. Water is a fluid which is always employed for this purpose, not only because it can be had without difficulty, but because it can be procured of the same temperature, and of the same density, in every part of the world. The specific gravity of water is always called 1.000, and with this, as a standard, the specific gravity of every other substance is compared. Thus, if a certain quantity of water weighed four pounds, and a similar quantity of mercury 54 pounds, the specific gravity of the mercury would be called $13\frac{1}{2}$, because as $4 : 54 = 1 : 13\frac{1}{2}$. In order, therefore, to determine the densities of bodies, we have occasion for no other instrument than a common balance with a hook fixed beneath one of its scales. When fitted up in this way, it has been called the *hydrostatic balance*, which has already been described under the article Balance, *Hydrostatical*.

Hydrostatic balance.

To find the specific gravity of a solid heavier than water.

111. *When the substance is heavier than its bulk of water.*—Suspend the solid by means of a fine silver wire to the hook beneath the scale, and find its weight in air. Fill a jar with pure distilled water, of the temperature of 62° of Fahrenheit's thermometer, and find the weight of the solid when immersed in this fluid. The difference of these weights is the loss of weight sustained by the solid. Then (96.), as the loss of weight is to the weight of the solid in air, so is 1.000 the specific gravity of water to a

Of Specific Gravities.

fourth proportional, which will be the specific gravity of the solid. But as the third term of the preceding analogy is always 1.000, the fourth proportional, or density of the solid, will always be had by dividing the weight of the solid in air by its loss of weight in water. If the solid substance consists of grains of platina or metallic filings, place it in a small glass bucket. Find the weight of the bucket in air, when empty, and also its weight when it contains the substance. The difference of these weights will be the weight of the substance in air. Do the very same in water, and its weight in water will be had. Its specific gravity will then be found as formerly. If the body is soluble in water, or so porous as to absorb it, it should be covered with varnish or some unctuous substance. When it is weighed in water, it should never touch the sides of the glass jar, and it must be carefully freed from any bubbles of air that happen to adhere to it.

To find the specific gravity of a solid lighter than water.

112. *When the substance is lighter than its bulk of water.*—Fasten to it another solid heavier than water, so that they may sink together. Find the weight of the denser body, and also of the compound body, both in air and in water; and by subtracting their weight in water from their weight in air, find how much weight they have severally lost. Then say as the difference between their losses of weight is to the weight of the light body in air, so is 1.000 to the specific gravity of the body.

To find the specific gravity of powders.

113. *When the substance is a powder which absorbs water, or is soluble in it.*—Place a glass phial in one scale, and counterpoise it by weights in the other. Fill this phial with the powder to be examined; and having rammed it as close as possible to the very top, find the weight of the powder. Remove the powder from the phial, and fill it with distilled water, and find its weight. The weight of the powder, divided by the weight of the water, will be the specific gravity of the former. See art. 124.

To find the specific gravity of fluids.

114. *When the substance is a fluid*, its specific gravity may be determined very accurately by the method in the preceding article, or by the following method, deduced from article 95.—Take any solid specifically heavier than water, and the given fluid. Find the loss of weight which it sustains in water, and also in the given fluid. Then, since the specific gravities are as the losses of weight sustained by the same solid, the specific gravity of the fluid required will be found by dividing the loss of weight sustained by the solid in the given fluid, by the loss of weight which it sustains in water.

SECT. II. *On the Hydrometer.*

Hydrometer invented by Hypatia.

115. In order to determine, with expedition, the strength of spirituous liquors, which are inversely proportional to their specific gravities, an instrument more simple, though less accurate, than the hydrostatic balance, has been generally employed. This instrument is called a *hydrometer*, sometimes an *areometer* and *gravimeter*, and very erroneously a *hygrometer* by some foreign authors. It seems to have been invented by Hypatia, the daughter of Theon Alexandrinus, who flourished about the end of the fourth century; though there is some foundation for the opinion that the invention is due to Archimedes.

Fahrenheit's hydrometer.

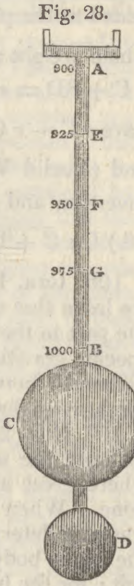
116. The hydrometer of Fahrenheit, which is one of the simplest that has been constructed, is represented in fig. 28, and may be formed either of glass or metal. A B is a cylindrical stem, and C, D two hollow balls appended to it. Into the lower ball D is introduced a quantity of mercury, sufficient to make the ball C sink to F, a little below the surface of distilled water. If this apparatus be plunged into a fluid lighter than water, the ball C will sink farther below the surface; and, if it be immersed in a heavier fluid, it will rise nearer the surface. In this way we can tell whether one fluid is more or less dense than another. But in order to determine the real specific gravities of the fluids, the hydrometer must either be loaded with different weights, or have a scale A B engraven on its stem. The former of these methods was employed by Fahrenheit. Having placed some small weights on the top A, he marked any point E, to which the instrument sunk in distilled water. By weighing the instrument thus loaded, he found the weight of a quantity of water equal to the part immersed (92). When the hydrometer was placed in a fluid denser than water, he loaded it with additional weights till it sunk to the same point E. The weight of the hydrometer being again found, gave him the weight of a quantity of the denser fluid equal to the part immersed; but as the part immersed was the same in both cases, the weights of the hydrometer were equal to the absolute weights of equal quantities of the two fluids; and, consequently, the specific gravities of the water and the other fluid were in the ratio of these weights. When the fluid, whose density is required, has less specific gravity than water, some of the weights are to be removed from the top A, till the instrument sinks to E; and the density of the fluid to be determined as before.

Hydrometer with weights.

—Instead of making the weight of the hydrometer variable, it is more simple, though less accurate, to have a scale of equal parts upon the stem AB. In order to graduate this scale, immerse the hydrometer in distilled water, at the temperature of 60° Fahrenheit, so that it may sink to B near the bottom of the stem, which may be easily effected, by diminishing or increasing the quantity of mercury in the ball D. At B place the number 1.000, which shews that every fluid, in which the hydrometer sinks to B, has its specific gravity 1.000, or that of distilled water. The hydrometer is then to be plunged in another fluid less dense than water, suppose oil, whose specific gravity may be .900, and the point A marked, to which it sinks. Every fluid, therefore, in which the hydrometer sinks to A, has its specific gravity .900; and if the scale AB be divided into equal parts, every intermediate degree of specific gravity between .900 and 1.000 will be marked. If the scale AB be divided into four parts in the points E, F, G, the fluid in which the hydrometer sinks to G will have .975 for its specific gravity; the specific gravity of that in which it sinks to F will be .950, and so on with the other points of division. If it is required to extend the range of the instrument, and to make it indicate the densities of fluids specifically lighter than water, we have only to load it in such a manner as to make it sink to the middle of the scale F in distilled water; and by taking two fluids, between whose densities the specific gravity of every other fluid is contained, excepting mercury and metals in a fluid state, to determine, as before, the extremities of the scale.

Hydrometer with an engraved scale.

Fig. 28.



Theorem for hydrometers in which the weight is variable.

117. When the weight of the hydrometer is variable, let E be the point to which it sinks in two different fluids; and let W be the absolute weight necessary to make it sink to E in the denser fluid, and $W \pm p$ the weight necessary to make it sink to the same point in the lighter fluid. Let S, s be the specific gravities of the two fluids, and V the volume of the part of the hydrometer that is constantly immersed. Then (99.) $W = \overline{S \times V}$, $W \pm p = s \times V$.

From the first equation we have, $V = \frac{W}{S}$, and from the

Of Specific Gravities.

second equation $V = \frac{W \pm p}{s}$, consequently $\frac{W \pm p}{s} = \frac{W}{S}$, and by reduction $s = \frac{s \times \overline{W \pm p}}{W}$. Thus, by knowing W and the weight p, and also S the specific gravity of one of the fluids, which will be 1.000 if that fluid be water, we can find s the specific gravity of the other fluid.

Theorem for hydrometers in which the weight is constant.

118. When the weight of the hydrometer is constant, and the density of the fluid indicated by the depth to which it descends, let F, E be the points to which it sinks in two different fluids, whose specific gravities are S, s, W the absolute weight of the hydrometer, V the volume of the part immersed when the hydrometer has sunk to E, and v its volume when sunk to F. Then (99.), we have $W = S \times V$, and $W = s \times v$, consequently $s \times v = S \times V$, and $s = \frac{S \times V}{v}$. If the absolute weight W, therefore, of the hydrometer be known, and also the volumes V, v, and the specific gravity S of one of the fluids, which may be water, the specific gravity of the other fluid may be determined by the preceding formula. When the figure of the hydrometer is regular, the volumes V, v, may be determined geometrically; but as the instrument is generally of an irregular form, the following methods should be employed:

Jones's Hydrometer.

Jones's hydrometer.

119. The hydrometer invented by Mr William Jones of Holborn, is a simple and accurate instrument, and requires only three weights to discover the strengths of spirituous liquors from alcohol to water. Like other instruments of the same kind, it is adjusted to the temperature of 60° of Fahrenheit; but as every change of temperature produces a change in the specific gravity of the spirits, Mr Jones found it necessary to attach a thermometer to the instrument, and thus make a proper allowance for every variation of temperature. Almost all bodies expand with heat and contract with cold; and as their volume becomes different at different temperatures, their specific gravities must also (86.) be variable, and will diminish with an increase of temperature. M. Homberg, and M. Eisenschmed found that the absolute weight of a cubic inch of brandy was four drams 42 grains in winter, and only four drams 32 grains in summer, and that the difference in spirits of nitre was still greater. It has been found, indeed, upon an average, that 32 gallons of spirits in winter will expand to 33 gallons in summer. As the strength of spirituous liquors is inversely as their specific gravities, they will appear much stronger in summer than in winter. This change in their strength had been formerly estimated in a rough way; but by the application of the thermometer, and by adjusting its divisions experimentally, Mr Jones has reduced it to pretty accurate computation. It has already been stated (109.) that where two substances are combined, the magnitude of the compound body is sometimes greater and sometimes less than the sum of the magnitudes of the two ingredients, and that this mutual penetration particularly happened in the mixture of alcohol and water. In strong spirits, this concentration is sometimes so great, as to produce a diminution of four gallons in the 100; for if to 100 gallons of spirit of wine found by the hydrometer to be 66 gallons in the 100 over proof, you add 66 gallons of water to reduce it to proof, the mixture will consist only of 162 gallons instead of 166 of proof spirits. This mutual penetration of the particles of alcohol and water has also been considered in Mr Jones's hydrometer, which we shall now describe with greater minuteness.

Of Specific Gravities.

120. In fig. 29. the whole instrument is represented with the thermometer attached to it. Its length AB is about $9\frac{1}{2}$ inches: the ball C is made of hard brass, and nearly oval, having its conjugate diameter about $1\frac{1}{2}$ inches. The stem AD is a parallelopiped, on the four sides of which the different strengths of spirits are engraved: the three sides which do not appear in fig. 29. are represented in fig. 30. with the three weights numbered 1, 2, 3, corresponding with the sides similarly marked at the top. If the instrument, when placed in the spirits, sinks to the divisions on the stem without a weight, their strength will be shewn on the side AD marked 0 at the top, and any degree of strength from 74 gallons in the 100 to 47 in the 100 above proof, will thus be indicated. If the hydrometer does not sink to the divisions without a weight, it must be loaded with any of the weights 1, 2, 3, till the ball C is completely immersed. If the weight No. 1. is necessary, the side marked 1 will shew the strength of the spirits, from 46 to 13 gallons in the 100 above proof. If the weight No. 2. is employed, the corresponding side will indicate the remainder of overproof to *proof*, marked P in the instrument, and likewise every gallon in 100 under proof, down to 29. When the weight No. 3. is used, the side similarly marked will shew any strength from 30 gallons in the 100 under proof, down to water, which is marked W in the scale. The small figures as 4 at 66, $3\frac{1}{2}$ at 61, $2\frac{1}{2}$ at 48 (fig. 29.) indicate the diminution of bulk which takes place when water is mixed with spirits of wine in order to reduce it to proof: thus, if the spirit be 61 gallons in the 100 over proof, and if 61 gallons of water are added in order to render it proof, the magnitude of the mixture will be $3\frac{1}{2}$ gallons less than the sum of the magnitudes of the ingredients, that is, instead of being 161 it will be only $157\frac{1}{2}$ gallons. The thermometer F connected with the hydrometer, has four columns engraved upon it, two on one side as seen in the figure, and two on the other side. When any of the scales upon the hydrometer, marked 0, 1, 2, 3, are employed, the column of the thermometer similarly marked must be used, and the number at which the mercury stands carefully observed. The divisions commence at the middle of each column which is marked 0, and is equivalent to a temperature of 60° of Fahrenheit; then, whatever number of divisions the mercury stands above the zero of the scale, the same number of gallons in the 100 must the spirit be reckoned weaker than the hydrometer indicates, and whatever number of divisions the mercury stands below the zero, so many gallons in the 100 must the spirit be reckoned stronger.

Fig. 29.

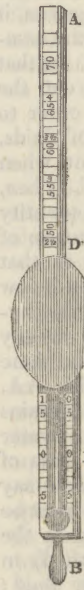


Fig. 30.

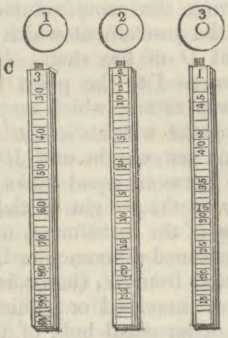


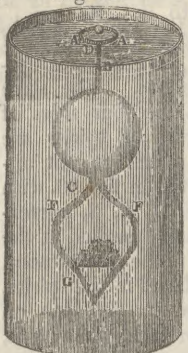
Nicholson's Hydrometer.

Nicholson's hydrometer.

121. A considerable improvement on the hydrometer has lately been made by Mr Nicholson, who has rendered it capable of ascertaining the specific gravities both of solids and fluids. F is a hollow ball of copper attached to the dish AA by a stem B, made of hardened steel. To the lower extremity of the ball is affixed a kind of iron stirrup FF, carrying another dish G of such a weight as to keep the stem vertical when the instrument is afloat. The parts

Of Specific Gravities.

Fig. 31.



of the hydrometer are so adjusted, that when the lower dish G is empty, and the upper dish AA contains 1000 grains, it will sink in distilled water at the temperature of 60° of Fahrenheit, so that the surface of the fluid may cut the stem DB at the point D. In order to measure the specific gravities of fluids, let the weight of the instrument, when loaded, be accurately ascertained. Then, this weight is equal to that of a quantity of distilled water at the temperature of 60°, having the same volume as that part of the instrument which is below the point D of the stem. If the hydrometer, therefore, is immersed to the point D in any other fluid of the same temperature, which may be done by increasing or diminishing the weights in the dish AA, the difference between this last weight and 1000 grains will express the difference between equal bulks of water and the other fluid. Now as the weight of the mass of water is equal to the weight of the instrument, which may be called W, the above-mentioned difference or D must be either added to or subtracted from W, (according as the weight in the dish AA was increased or diminished) in order to have the weight of an equal bulk of the fluid; then $W \pm D$ will be to W as the specific gravity of the given fluid is to that of water. This ratio will be expressed with considerable accuracy, as the cylindrical stem of the instrument being no more than $\frac{1}{40}$th of an inch in diameter, will be elevated or depressed nearly an inch by the subtraction or addition of $\frac{1}{10}$ of a grain, and will, therefore, easily point out any changes of weight, not less than $\frac{1}{20}$ of a grain, or $\frac{1}{20000}$ of the whole, which will give the specific gravities to five places of figures. The solid bodies whose specific gravities are to be determined by this hydrometer, must not exceed 1000 grains in weight. For this purpose, immerse the instrument in distilled water, and load the upper dish AA till the surface of the water is on a level with the point D of the stem. Then, if the weights required to produce this equilibrium be exactly 1000 grains, the temperature of the water will be 60° of Fahrenheit; but if they be greater or less than 1000 grains, the water will be colder or warmer. After noting down the weight necessary for producing an equilibrium, unload the upper dish, and place on it the body whose specific gravity is required. Increase the weight in the upper dish, till the instrument sinks to the point D, and the difference between this new weight and the weight formerly noted down, will be the weight of the body in air. Place the body in the lower dish G, and add weights in the upper dish till the hydrometer again sinks to D. This weight will be the difference between 1000 grains and the weight of the body in water; and since the weight of the body in air, and its weight in water, are ascertained, its loss of weight will be known, and consequently its specific gravity (96).

Wilson's Beads.

Wilson's, hydrometric beads.

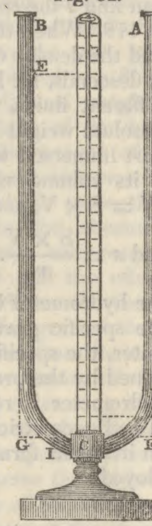
122. In order to determine the strength of spirits with the greatest expedition, Professor Wilson of Glasgow employed a very simple method. His hydrometer consists of a number of glass beads, the specific gravities of each of which vary in a known ratio. When the strength of any spirit is to be tried, the glass beads, which are all numbered, are to be thrown into it. Some of those whose specific gravity exceeds that of the spirit will sink to the bottom, while others will swim on the top, or remain suspended in the fluid. That which neither sinks to the bottom nor swims on the surface, will indicate by its number the specific gravity of the spirits (78). These beads have been greatly improved by Mrs Lovi, and are numbered in a variety of ways, either to shew specific gravities or the strength of spirits.

Of Specific Gravities.

Barometrical Areometer.

Barometrical areometer.

Fig. 32.



123. This name may be appropriately given to an instrument which is more useful for the purposes of illustration than of measurement. If two immisceable liquids are poured into a two-branched tube ABC, the one into the branch BC, and the other into the branch AC, till they balance each other, their specific gravities will be to one another inversely as the heights of each column. Thus, if we pour in mercury at A, and water at B, so that when the surface of the mercury is at D, that of the the water is at E, we shall find that if the column of mercury DF is two inches, that of the water EG will be 27 inches, and their specific gravities will be as 27 to 2, or as $13\frac{1}{2}$ to 1. If we pour in at B lintseed oil in place of water, the height EF will be 29 inches, and the specific gravity of the oil 0.931; because $\overset{\text{Feet.}}{27} : \overset{\text{In.}}{2} = 13\frac{1}{2} : 0.931$. By thus using mercury as the balancing column, the specific gravities of all fluids that do not mix with it, or act upon it, may be readily ascertained. The results thus obtained are not affected by the admission of the air at the open ends A and B, because the same weight of air presses upon the two balancing columns. But if we pour in mercury at A till the bent tube ACB contains above thirty inches of it, and close up the end A, and remove the air from above the mercury in AC, the column of mercury being no longer pressed down by the air in AC, will be pressed up to near the top of the tube AA by the pressure of the column of air in BC, and the instrument becomes a barometer, a column of air balancing a column of mercury. In this case, the tube BI becomes unnecessary, and the mercury may be enclosed in a glass ball at I, with an opening to admit the air.

Say's Stereometer.

Say's stereometer.

124. Captain M. K. Say, of the French Engineers, invented a very ingenious instrument for measuring the specific gravity of liquid bodies, soft bodies, *porous bodies*, and *powders*, as well as that of solids; and he published a detailed description of it, illustrated with various figures, in the *Annales de Chimie* for 1797.[1]

Many years afterwards, Professor Leslie brought forward the same instrument, under the name of a *Coniometer*, as a new invention, but without any variation of the principle. The following general description will give our readers an idea of the very beautiful principle on which this instrument is founded: Let AE be a glass tube, about three feet long, and open at both ends, the upper part AB being about 4-10ths, and the lower part BE about 2-10ths, of an inch in diameter. The upper edge of the tube is ground smooth, so that it can be shut air-tight by a piece of ground plate-glass, and the upper tube AB communicates with the lower one by a very narrow slit at B, which allows air to pass through it, but prevents sand or powder from passing.

The powder, sand for example, is put into the tube AB, and the lower tube BE is plunged into the open vessel F, containing mercury, till the mercury rises exactly within

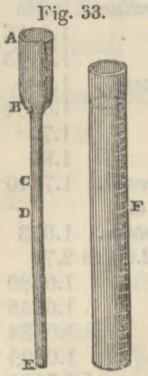
[1] See also *Nicholson's Journal*, 4to, vol. i. p. 325.

Of Specific Gravities.

the tube BE to the slit at B. The ground-glass cover is then placed air-tight upon the mouth A. There is now no air in the tube AE, except that which is mixed with the sand in the tube AB. If we now suppose that the atmospherical pressure indicated by the barometer is 30 inches, and elevate the tube AE till the mercury stands within it at a point C, 15 inches (one-half of 30), above its surface in the open vessel F, it is manifest that the air within the tube is pressed with exactly half an atmosphere, and therefore expands to twice its original bulk. Owing to this expansion of the air to twice its bulk, the tube AB contains only half the quantity of air which it did at first; and as the part BC contains the other half, the quantity of air in AB and BC is equal, as the air in BC is equal to the air that is mixed with the sand in AB, and fills the same space which the whole occupied previous to its expansion.

Let the sand be now removed from AB, and the same experiment repeated when the tube AB is filled with air. The quantity of air being now greater, will, when expanded to twice its bulk under a pressure of 15 inches, fill a larger space than BC, and the mercury will rise only to some point D. But as the expanded air in E occupies exactly the very same space in BC or BD that the whole occupied in AB under the ordinary atmospheric pressure of 30 inches, it follows that the cavity CD = BD — BC is equal to the bulk of the solid matter in the sand or powder. If we now find the number of grains of water held by the part CD of the tube, we determine at once the quantity of water equal in bulk to the solid matter in the sand or powder; and by comparing this with the weight of the sand, we obtain its exact specific gravity.

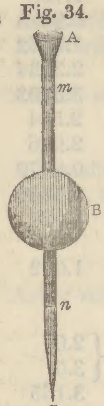
Fig. 33.



Brewster's Staktometer.

Brewster's staktometer.

Fig. 34.



125. The Staktometer, or *drop-measurer*, is shewn in fig. 34, where ABC is a glass vessel four or five inches long, having a hollow bulb B about half an inch in diameter. The instrument is filled by suction, and the fluid is discharged at C till it stands nearly at the point m, the zero of the scale. The fluid is then allowed to discharge itself at C by drops, and the number of them is counted till the surface of the fluid descends to another fixed point n. The experiment is then carefully repeated at different temperatures, till the number of drops of distilled water occupied by the cavity between m and n is accurately determined for various temperatures. The same experiment is made with alcohol. Thus, if N is the number of drops of distilled water whose specific gravity is $S_{,}$, and n the number of drops of alcohol whose specific gravity is $s_{,}$, and d the number of drops of any other mixture of alcohol and water contained in the same cavity $m\,n$, we shall have $n - N : S - s = d - N : \frac{(d - N)(S - s)}{n - N}$; and therefore $S - \frac{(d - N)(S - s)}{n - N}$ will be the specific gravity of the mixture required.

With a small instrument, the number of drops of *water* between m and n was 724, whereas the number of drops of ordinary proof spirits was 2117 at 60° Fah. Now, as the specific gravity of the spirits was .920, and that of water 1.000, we have a scale of 1393 drops for measuring all specific gravities between .920 and 1000, an unit in the fourth place of decimals corresponding to a variation of about two drops. From this experiment it follows that the bulk of a drop of water will be about 2.93 times as large as the bulk of a drop of the spirits.

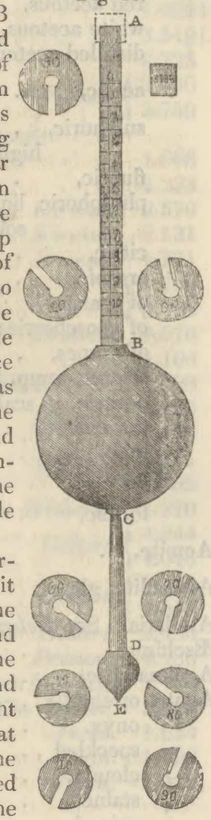
Of Specific Gravities.

Sikes's Hydrometer.

Sikes's hydrometer

126. This instrument, which is used in the collection of the revenue of the United Kingdom, is shewn in the annexed figure, where AB is a flat stem $3\frac{1}{2}$ inches long, divided on each side into eleven parts, each of which is divided into two. This stem carries a brass ball BC, into which is fixed the conical stem CD, terminating in a loaded bulb DE. Eight circular weights, numbered as in the figure, can be placed on the conical stem CD. The square weight can be placed on the top of the stem. When the strength of spirits is to be measured, a weight is to be placed on CD capable of sinking the ball BC till the fluid surface cuts the stem AB. The number at the place where the stem is cut by the fluid, as seen from below, is then added to the number on the weight employed; and with this sum at the side, and the temperature of the spirits at the top, the strength per cent. is found in a table which accompanies the instrument.

Fig. 35.



The square weight shews the difference between the weight of proof spirit and that of water, as described in the first clause of the hydrometer act; and it is exactly *one-twelfth* part of the total weight of the hydrometer and weight 60. When this square weight is placed on the summit of the stem at A, and the instrument loaded with the weight No. 6, it will sink in distilled water at the temperature 51° to the proof point P, at that temperature, as indicated on the narrow edge of the stem.

SECT. III. *On Tables of Specific Gravities.*

Table of specific gravities.

127. As the knowledge of the specific gravities of bodies is of great use in all the branches of mechanical philosophy, we have given the following table, comprehending the greater part of Brisson's tables, and one of the most extensive that has yet been published. When the specific gravities of any substance, as determined by different authors, seem to be at variance, the different results are frequently given, and the names of the observers prefixed by whom these results were obtained. The substances in the table have, contrary to the usual practice, been disposed in an alphabetical order. This was deemed more convenient for the purposes of reference, than if they had been divided into classes, or arranged according to the order of their densities.

The specific gravities of newly discovered minerals have been collected and inserted. The numbers are given in relation to water whose specific gravity is 1.000, excepting in the case of the gases, whose specific gravities are given in relation to that of atmospheric air, which is taken at 1.00.

[1] The specific gravities of the gases are taken from Biot's *Traité de Physique*, tom. i. p. 383; from Gay Lussac's Tables in the *Annales de Chimie et de Physique*, vol. i. p. 218; and from Thomson's *Annals of Philosophy*, vol. i. p. 118. The measures for the gases, taken by MM. Biot and Arago, are calculated from Biot's formulæ. They are given in relation to atmospheric air, which is supposed to be unity.

CHAPTER III.—ON CAPILLARY ATTRACTION, AND THE COHESION OF FLUIDS.

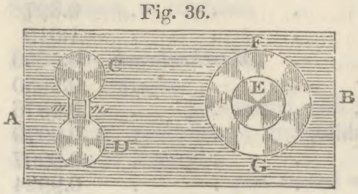
Fluids do not rise to the same level in a system of communicating vessels when their diameters are very minute.

128. We have already seen, when discussing the equilibrium of fluids, that when water or any other fluid is poured into a vessel, or any number of communicating vessels, its surface will be horizontal, or it will rise to the same height in each vessel, whatever be its form or position. This proposition, however, only holds true when the diameter of these vessels or tubes exceeds the fifteenth of an inch: for if a system of communicating vessels be composed of tubes of various diameters, the fluid will rise to a level surface in all the tubes which exceed one fifteenth of an inch in diameter; but in the tubes of a smaller bore, it will rise above that level to altitudes inversely proportional to the diameters of the tubes. The power by which the fluid is raised above its natural level is called *capillary attraction*, and the glass tubes which are employed to exhibit its phenomena are named *capillary tubes*. These appellations derive their origin from the Latin word *capillus*, signifying a hair, either because the bores of these tubes have the fineness of a hair, or because that substance is itself supposed to be of a tubular structure.

There is an attraction of cohesion between glass and water, and between the particles of water.

129. When we bring a piece of clean glass in contact with water or any other fluid, except mercury and fused metals, and withdraw it gently from its surface, a portion of the fluid will not only adhere to the glass, but a small force is necessary to detach this glass from the fluid mass, which seems to resist any separation of its parts. Hence it is obvious that there is an attraction of cohesion between glass and water, and that the constituent particles of water have also an attraction for each other. The suspension of a drop of water from the lower side of a plate of glass is a more palpable illustration of the first of these truths; and the following experiment will completely verify the second. Place two large drops of water on a smooth metallic surface, their distance being about the tenth of an inch. With the point of a pin unite these drops by two parallel canals, and the drops will instantly rush to each other through these canals, and fill the dry space that intervenes. This experiment is exhibited in fig. 36, where AB is the metallic plate, C, D the drops of water, and m, n, the two canals.

Fig. 36.



Attempt to account for the rise of water in capillary tubes. Fig. 36.

130. Upon these principles many attempts have been made to account for the elevation of water in capillary tubes; but most of the explanations which have hitherto been offered, are founded upon hypothesis, and are very far from being satisfactory. Without presuming to substitute a better explanation in the room of those which have been already given, and so frequently repeated, we shall endeavour to illustrate that explanation of the phenomena of capillary attraction which seems liable to the fewest objections. For this purpose let E be a drop of water laid upon a clean glass surface AB. Every particle of the glass immediately below the drop E, exerts an attractive force upon the particles of water. This force will produce the same effect upon the drop as a pressure in the opposite direction, the pressure of a column of air, for instance, on the upper surface of the drop. The effect of the attractive force, therefore, tending to press the drop to the glass will be an enlargement of its size, and the water will occupy the space FG; this increase of its dimensions will take place when the surface AB is held downwards; and that it does not arise from atmospheric pressure may be shewn by performing the experiment *in vacuo*. Now, let A B (fig. 37.) be a section of the plate of glass, AB (fig. 36.) held vertically, part of the water will descend by its gravity, and form a drop B, while a small film of the fluid will be supported at m by the attraction of the glass. Bring a similar plate of glass CD, into a position parallel to AB, and make them approach

Fig. 37.

apillary traction, &c.

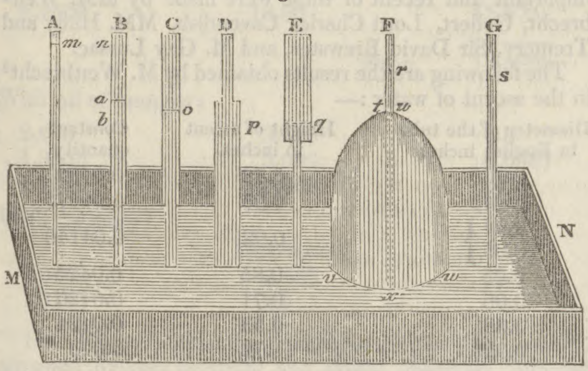
nearer and nearer each other. When the drops B and D come in contact, they will rush together from their mutual attraction, and will fill the space $o\ p$. The gravity of the drops B and D being thus diminished, the films of water at m and n, which were prevented from rising by their gravity, will move upwards. As the plates of glass continue to approximate, the space between them will fill with water, and the films at m and n being no longer prevented from yielding to the action of the glass immediately below them, (by the gravity of the water at $o\ p$, which is diminished by the mutual action of the fluid particles) will rise higher in proportion to the approach of the plates. Hence it may be easily understood how the water rises in capillary tubes, and how its altitude is inversely as their internal diameters. For let A, a be the altitudes of the fluid in two tubes of different diameters D, d; and let C, c be the two cylinders of fluid which are raised by virtue of the attraction of the glass. Now, as the force which raises the fluid must be as the number of attracting particles, that is, as the surface of the tube in contact with the water, that is, as the diameter of the tubes, and as this same force must be proportional to its effects on the cylinder of water raised, we shall have $D : d = C : c$. But (GEOMETRY, Sect. VIII. Theor. XI. Sect. IX. Theor. II.) $C : c = D^2A : d^2a$, therefore $D^2A : d^2a = D : d$; hence $D^2A\ d = d^2a\ D$, and $DA = \frac{d^2aD}{Dd}$, or $DA = da$, that is, $D : d = a : A$, or the altitudes of the water are inversely as the diameters of the tubes. Since $DA = da$, the product of the diameter by the altitude of the water will always be a constant quantity. In a tube whose diameter is 0.01, or $\frac{1}{100}$ of an inch, the water has been found to reach the altitude of 5.3 inches; hence the constant quantity $5.3 \times 0.1 = 0.053$ may fitly represent the attraction of glass for water. According to the experiments of Muschenbroek, the constant quantity is 0.039; according to Weitbrecht 0.0428; according to Monge 0.042, and according to Atwood 0.0530. When a glass tube was immersed in melted lead, Gellert found the depression multiplied by the bore to be 0.0054.

he altitudes of luids in pillary ibes are versely their ameters.

henomena of capillary attraction.

131. Having thus attempted to explain the causes of capillary action, we shall now proceed to consider some of its more interesting phenomena. In fig. 38. MN is a vessel of water in which tubes of various forms are immersed. The water will rise in the tubes A, B, C, to different altitudes m, n, o, inversely proportional to their diameters. If the tube B is broken at a, the water will not rise to the very top of it at a, but will stand at b, a little below the top, whatever be the length of the tube, or the diameter of its bore. If the tube be taken from the fluid and laid in a horizontal position, the water will recede from the end that was immersed. These two facts seem to countenance the opinion of Dr Jurin[1] and other philosophers, that the water is elevated in the tube by the attraction of the annulus, or ring of glass, *immediately above* the cylinder of water. This hypothesis is sufficiently plausible; but supposing it to be true, the ring of glass immediately below the surface of the cylinder of fluid should produce an equal and opposite effect, and therefore the water instead of rising should be stationary, being influenced by two forces of an equal and opposite kind.

Fig. 38.



Jurin's hypothesis.

Phenomena of capillary attraction.

132. If a tube D composed of two cylindrical tubes of different bores be immersed in water with the widest part downwards, the water will rise to the altitude p, and if another tube E of the same size and form be plunged in the fluid with the smaller end downwards, the water will rise to the same height q as it did in the tube D. This experiment seems to be a complete refutation of the opinion of Dr Jurin, that the water is raised by the action of the annulus of glass above the fluid column; for since the annular surface is the same at q as at p, the same quantity of fluid ought to be supported in both tubes, whereas the tube E evidently raises much less water than D. But if we admit the supposition in art. 130, that the fluid is suported by the whole surface of glass in contact with the water, the phenomenon receives a complete explanation; for since the surface of glass in contact with the fluid in the tube E is much less than the surface in contact with it in the tube D, the quantity of fluid sustained in the former ought to be much less than the quantity supported in the latter.

Phenomena of capillary attraction. Fig. 38.

133. When a vessel F vw, fig. 38. is plunged in water, and the lower part $tuvw$ filled by suction till the fluid enter the part F t, the water will rise to the same height as it does in the capillary tube G, whose bore is equal to the bore of the part F t. In this experiment the portions of water tvx and uxw on each side of the column F x are supported by the pressure of the atmosphere on the surface of the water in the vessel MN; for if this vessel be placed in the exhausted receiver of an air-pump, these portions of water will not be sustained. Dr Jurin, indeed, maintains that these portions will retain their position *in vacuo*, but in his time the exhausting power of the air-pump was not sufficiently great to determine a point of so great nicety. The column tux, which is not sustained by atmospherical pressure, is kept in its position by the attraction of the water immediately around and above it, and the column F tu is supported by the attraction of the glass surface with which it is in contact. According to Dr Jurin's hypothesis, the column tux is supported by the ring of glass immediately above r, which is a very unlikely supposition.

Hypothesis of Dr Hamilton and Dr Matthew Young.

134. The preceding experiment completely overturns the hypothesis of Dr Hamilton, afterwards revived by Dr Matthew Young. These philosophers maintained that the fluid was sustained in the tube by the lower ring of glass contiguous to the bottom of the tube, that this ring raises the portion of water immediately below it, and then other portions successively till the portion of water thus raised be in equilibrium with the attraction of the annulus in question. But if the elevation of the fluid were produced in this way, the quantity supported would be regulated by the form and magnitude of the orifice at the bottom of the tube; whereas it is evident from every experiment, that the cylinder of fluid sustained in capillary tubes has no reference whatever to the form of the lower annulus, but depends solely upon the diameter of the tube immediately above the elevated column of water.

These phenomena occur in an exhausted receiver.

135. If the experiments which we have now explained be performed in the exhausted receiver of an air-pump, the water will rise to the same height as when they are

[1] *Philosophical Transactions*, No. 363, Art. 2.

performed in air. We may therefore conclude, that the ascent of the water is not occasioned, as some have imagined, by the pressure of the atmosphere acting more freely upon the surface of the water in the vessel than upon the column of fluid in the capillary tube.

Experiments of M. Louis Carré on the ascent of different fluids in capillary tubes.

136. Numerous experiments have been made on the ascent of water and other fluids in capillary tubes. Among the earliest of these we may enumerate the experiments of M. Louis Carré, which were made previous to 1705. He found that in a tube *twelve* inches long water rose 10 lines, when the diameter of the tube was $\frac{1}{3}$ of a line, 18 lines when its diameter was $\frac{1}{6}$, and 30 lines when its diameter was $\frac{1}{10}$ of a line.

The following are the results which he obtained with different fluids, and with a glass tube *twelve* inches in length:

Names of Fluids.	Diameter of the glass tube in parts of a line.	Height of ascent in lines.
Water,	$\frac{1}{3}$ of a line.	10
Alcohol,		$3\frac{1}{2}$
Spirits of turpentine,		4
Oil of tartar,		5
Spirit of nitre,		4
Oil of olives,		5
Tube 9 Inches long.		
Water,	$\frac{1}{3}$ of a line.	10
Alcohol,		4
Tube 15 Inches long.		
Water,	$\frac{1}{6}$ of a line.	29
Alcohol,		12
Tube 5 Inches long.		
Water,	$\frac{1}{6}$ of a line.	27
Alcohol,		12 nearly.

Experiments of Mr B. Martin

137. The following experiments were made by Mr Benjamin Martin with a tube about $\frac{1}{25}$ of an inch in diameter:[1]

Names of the Fluids.	Height of Ascent in inches.	Constant Number.
Common spring water,	1.2	.048
Spirit of urine,	1.1	.044
Tincture of galls,	1.1	.044
Recent urine,	1.1	.044
Spirit of salt,	0.9	.036
Ol. tart. per deliq.	0.9	.036
Vinegar,	0.95	.038
Small beer,	0.9	.036
Strong spirit of nitre,	0.85	.034
Spirit of hartshorn,	0.85	.034
Cream,	0.8	.032
Skimmed milk,	0.8	.032
Aquafortis,	0.75	.030
Red wine,	0.75	.030
White wine,	0.75	.030
Ale,	0.75	.030
Ol. sul. per campanam,	0.65	.026
Oil of vitriol,	0.65	.026
Sweet oil,	0.6	.024
Oil of turpentine,	0.55	.022
Geneva,	0.55	.022
Rum,	0.5	.020
Brandy,	0.5	.020
White hard varnish,	0.5	.020
Spirit of wine,	0.45	.018
Tincture of mars,	0.45	.018

138. To the preceding table as given by Mr Martin we have added the constant number for each fluid, or the product of the altitude of the liquid, and the diameter of the tube (art. 130). By this number, therefore, we can find the altitude to which any of the preceding fluids will rise in a tube of a given bore, or the diameter of the bore when the altitude of the fluid is known; for since the constant number $C = DA$ (art. 130.) we shall have $D = \frac{C}{A}$ and $A = \frac{C}{D}$. Since the constant number, however, as deduced from the experiments of Martin, may not be perfectly correct, it would be improper to derive from it the diameter of the capillary bore when great accuracy is necessary.

Method of measuring the internal diameter of a capillary tube.

The following method, therefore, may be adopted as the most correct that can be given. Put into the capillary tube a quantity of mercury, whose weight in troy grains is W, and let the length L of the tube which it occupies be accurately ascertained; then if the mercury be pure and at the temperature of 60° of Fahrenheit, the diameter of the tube $D = \sqrt{\frac{W}{L}} \times 0.019241$, the specific gravity of mercury being 13.580. The weight of a cubic inch of mercury being 3438 grains, and the solid contents of the mercurial column being $D^2 L \times 0.7854$, we shall have $1 : 3438 = D^2 L \times 0.7854 : W$. Hence (GEOMETRY, Sect. IV. Theor. VIII.) $D^2 L \times 0.7854 \times 3438 = W$, and dividing we have $D^2 = \frac{W}{L \times 0.7854 \times 3438}$ or $D = \sqrt{\frac{W}{L \times 0.7854 \times 3438}}$ or $D = \sqrt{\frac{W}{L}} \times 0.019241$. If the whole tube be filled with mercury, and if W be the difference in troy grains between its weight when empty, and when filled with mercury, the same theorem will serve for ascertaining the diameter of the tube. Should the temperature of the mercury happen to be 32° of Fahrenheit, its specific gravity will be 13.619, which will alter a very little the constant multiplier 0.019241.

139. Various experiments on the ascent of fluids in capillary tubes have been made by different individuals. The most important and recent of these were made by MM. Weitbrecht, Gellert, Lord Charles Cavendish, MM. Haüy and Tremery, Sir David Brewster, and M. Gay Lussac.

Experiments of Weitbrecht.

The following are the results obtained by M. Weitbrecht[2] in the ascent of water:—

Diameter of the tube in English inches.	Height of ascent in inches.	Constant quantity.
0.065	0.72	0.0432
0.045	0.95	0.04275
0.04 / 0.05	0.92	0.04140
0.05	0.85	0.0425
0.06	0.71	0.0426
0.08	0.53	0.0424
0.025	1.72	0.043
	Mean,	0.04255

Of Gellert.

140. A series of experiments were made in 1740 by M. Gellert, on the descent of melted lead in capillary tubes of glass. For this purpose he used the thinnest tubes, and heating them gradually before immersion in the lead, he obtained the following measures:—

[1] Mr Martin found, that when capillary tubes, containing different fluids, were suspended in the sun for months together, the inclosed fluid was not in the least degree diminished by evaporation.

[2] *Comment. Acad. Petrop.* 1736.

apillary traction, &c.

Diameter of tube.	Descent.	Constant quantity.
0.21 English inch,	0.27 inch,	567
0.07 ...	0.73 ...	510
	Mean, .	5385

M. Gellert likewise made experiments on the ascent of *water* in prismatic tubes, with a triangular and quadrangular bore, made of iron, and he found that they gave results analogous to those obtained with tubes of glass.

xperiments of ord harles avendish.

141. The most accurate experiments on the depression of mercury in capillary tubes are those made by Lord Charles Cavendish:

Interior diameter of tube.	Mercury in one inch of tube.	Depression of the mercury.
0.6 inches.	972 grains.	0.005 inches.
0.5	675	0.007
0.4	432	0.015
0.35	331	0.025
0.30	243	0.036
0.25	169	0.050
0.20	108	0.067
0.15	61	0.092
0.10	27	0.140

The constant quantity deduced by Dr Thomas Young from the preceding experiments is 0.015.

xperiments of r Robin.

142. The following experiments were made by Dr Robison, on the ascent of different fluids in a glass tube of a very slender bore, but its diameter is not mentioned.

	Height of ascent.
Solution of sal ammoniac, .	8.07 inches.
Caustic volutile alkali, . .	6.25
Water, ...	5.5
Spirits of wine, . . .	2.5
Oil of turpentine, . .	1.35

aüy and remery's periments.

143. A series of careful experiments was made by MM. Haüy and Tremery, at the request of La Place, on the ascent of water and oil of oranges in glass tubes; and also on the depression of mercury. The following results were obtained with water:

Diameter of tube.	Height of ascent.	Constant quantity, or height for 1 millimetre.
2.0000 millimetres.	6.75 millimetres.	13.50
1.3333	10.00	13.333
0.7500	18.50	13.875
	Mean,	13.5693

With oil of oranges:

2.000	3.400	6.8
1.3333	5.000	6.6667
0.7500	9.000	6.75

With mercury:

	Depression.
2.0000	3.666
1.3333	5.5

rewster's xperiments on pillary traction.

144. The very great discrepancy in the preceding results, obtained by very accurate and skilful observers, induced Sir David Brewster to repeat the experiments with an instrument constructed for the purpose, and to take such precautions, that he could always obtain the same results after repeated trials. The following description of the instrument which he used, and of the precautions which he adopted, will enable the reader to judge of the accuracy of the results.

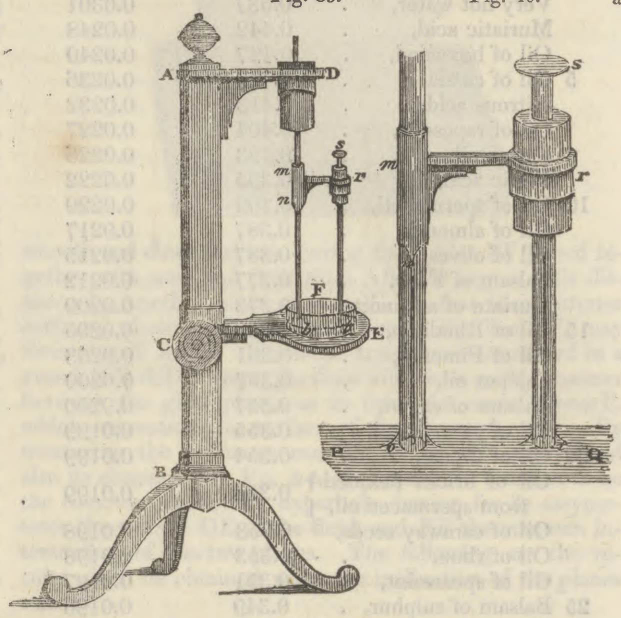
Having obtained a glass tube 7.9 inches long, and of a uniform circular bore, he took a wire of a less diameter than the bore of the tube, and formed a small hook at one of its ends. This hook was fastened to the middle of a worsted thread, of such a size as, when doubled, to fill the bore of the tube. The wire was then passed through the tube, and the worsted thread drawn after it; and when the whole was plunged in an alkaline solution, the worsted thread was fixed at one end, and the tube was drawn backwards and forwards, till it was completely deprived, by its friction on the thread, of any grease or foreign matter which might have adhered to it. The tube and thread were then taken to clean water, and the same operation was repeated.

Capillary Attraction, &c.

Instrument for measuring capillary attraction.

When the tube was thus perfectly cleaned, it was fixed vertically, by means of a level, in the axis of a piece of wood D (fig. 39.), supported by the arm AD, fixed upon

Fig. 39. Fig. 40.



a stand AB; and it was also furnished with an index *mn*, which was moveable to and from the extremity *b*. On the arm CE, moveable in a vertical direction by the nut C, was placed a glass vessel F, containing the fluid, and nearly filled with it. The nut C was then turned till the extremity *b* of the tube touched the surface of the fluid, which was indicated by the sudden rise of the liquor round its sides. The fluid then rose in the tube till it remained stationary, and the index *mn* was moved till its extremity *n* pointed out the exact position of the upper surface of the fluid. In this situation, the distance *nb* was a measure of the ascent of the liquid above its level in the vessel E. In order to ascertain, however, whether the fluid was stationary, in consequence of any obstruction in the tube, or of an equilibrium of the attracting forces, the vessel with the fluid was raised a little higher than its former position, by means of the nut C, and then depressed below it. If the fluid now rose a little above *n*, and afterwards sunk a little below it, so as always to rise and fall with facility and uniformity along with the surface of the fluid in the vessel, it was obvious that it suffered no obstruction in the tube, and that *nb* was the accurate measure of its height. By separating the extremity *b* of the tube from the surface of the fluid, the fluid always rises above *n*; but upon again bringing them into contact, the fluid resumes its position at *n*. If there should be any portion of fluid at the end *b* of the tube, when it is again brought in contact with the fluid surface, the water would rise around it before it had reached the general level, and therefore the height of the fluid obtained measuring from the end of the tube would be too small.by

In order to avoid this source of error, the index should have a projecting arm *mn*, Fig. 40, carrying a screw *st*, whose sharp point *t* can be easily brought on a level with the end *b* of the tube. When the extremity *t*, therefore, which can always be kept dry, comes in contact with the fluid surface PQ, the extremity *b* must also be exactly on the same level, even though the fluid had already risen around it. The tube was then cleaned, as formerly, for a subsequent observation. The results which were thus obtained for a great variety of fluids, and with a tube 0.0561 of an inch in diameter, are given in the following table:—

	Names of Fluids.	Height of Ascent, in inches.	Constant Quantity.
	Water,	0.587	0.0327
	Very hot water,	0.537	0.0301
	Muriatic acid,	0.442	0.0248
	Oil of boxwood,	0.427	0.0240
5	Oil of cassia,	0.420	0.0236
	Nitrous acid,	0.413	0.0232
	Oil of rapeseed,	0.404	0.0227
	Castor oil,	0.403	0.0226
	Nitric acid,	0.395	0.0222
10	Oil of spermaceti,	0.392	0.0220
	Oil of almonds,	0.387	0.0217
	Oil of olives,	0.387	0.0215
	Balsam of Peru,	0.377	0.0212
	Muriate of antimony,	0.373	0.0209
15	Oil of Rhodium,	0.366	0.0205
	Oil of Pimento,	0.361	0.0203
	Cajeput oil,	0.357	0.0200

Gay Lussac's experiments.

145. By means of an instrument similar in principle to the one above described,[2] M. Gay Lussac made a series of accurate experiments on the ascent of water and alcohol in capillary tubes. In these experiments the tubes were well wetted with the fluid.

Experiments with Water.

Diameter of the tube.	Height of ascent above lowest point of concavity.	Temp. of fluid. Centigrade.
1.29441 millim.	23.3164 millim.	
1.90381	15.5861	8°.5

The constant quantity in English inches, as deduced from these two experiments, is 0.04622.

Experiments with Alcohol.

Diameter of the tube.	Height of ascent above lowest point of concavity.	Density of alcohol.
1.29441 millim.	9.18235 millim.	0.81961
1.90381	6.08397	0.81961
1.29441	9,30079	0.8595
1.29441	9,99727	0.94153
[3] 10.508	0.3835	0.81347

The temperature of the alcohol was 8°.5 centig., and the constant quantity for the two first experiments, reduced to English inches, is 0.01815, which agrees remarkably with 0.0178, the constant quantity in Sir David Brewster's experiments.

Experiments with Oil of Turpentine.

Diameter of tube.	Height of fluid.	Density.
1.29441 millim.	9.95159	0.869458

This result also coincides very nearly with that of Sir David Brewster.

General results.

146. The following table contains a general view of the results obtained by different philosophers, from the ascent of *water* in capillary tubes.

Names of observers.	Constant quantity, in English inches.
Sir Isaac Newton,[4]	0.020
MM. Haüy and Tremery,	0.021
M. Carré, mean of three observations,	0.022
M. Hallstrom,	0.026
Sir David Brewster,	0.033
Muschenbroek,	0.039
M. Weitbrecht, average of his results,	0.042
M. Gay-Lussac, average of 2 observations,	0.046
Benjamin Martin,	0.048
Mr Atwood,	0.053
James Bernoulli,	0.064

Cause of the discrepancies in the measures.

Throwing aside the measure of James Bernouilli as obviously erroneous, we obtain 0.035 as the general average result of the preceding means; but the difference between this and the extreme measures of Newton and Atwood is so great, that there must be some cause, different from an error of observation, to which it is owing. The difference between the results obtained by Sir David Brewster and M. Gay-Lussac, made with nice instruments founded on the same principle, leads to the same conclusion. La Place indeed has ascribed, and we think justly, these differences to the *greater* or *less* degree of humidity on the sides of the tubes; and he informs us that Gay Lussac made his experiments with tubes *very much wetted*. Here, then, we have at once the cause of the difference above mentioned, because the experiments of Sir David Brewster

[1] Dr Young found the height of ascent of water and diluted spirit of wine to be as 100 to 64.

[2] See Biot's *Traité de Physique.*

[3] This is a mean of *five* experiments.

[4] *Optics*, p. 366, 3d edition.

Capillary Attraction, &c.

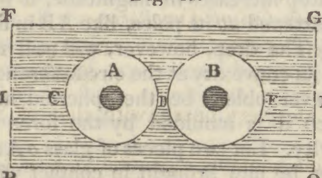
were made with a tube *carefully cleaned and dried after each experiment.* A dry tube must necessarily raise the water to a less height than a wet one, and the difference must increase as the diameter of the tube employed is diminished. If we conceive a tube, indeed, with an exceedingly small bore, wetted over the whole of its interior, in the slightest degree, the *two* inner surfaces of the film would nearly meet in the axis, and the height of ascent would be infinite, or as high as the tube was long.

147. From these observations, the reader will be already prepared to draw the conclusion, that the ascent of fluids in glass tubes is a very equivocal measure of the force of capillary attraction, independent of its being applicable only to the single substance of glass.

Different method of measuring capillary attraction.

With the view of removing this objection, Sir David Brewster long ago constructed an instrument, the object of which was to measure, upon an optical principle, the diameter of the circle of fluid which any cylindrical solid raises by capillary attraction above its general level. Thus let MN (fig. 41.) be the plan of a vessel filled with fluid, and A the section of a vertical cylinder of well cleaned and well dried glass, or any other substance not porous. This solid A will raise the fluid to a certain height around it, elevating a circular portion CD of the fluid above the general level; and it is manifest that the diameter CD of this elevated portion will be proportioned to the height of the fluid round the sides of the cylinder, or to the capillary force by which it is raised. In order to measure the diameter of this circle of fluid, a micrometer carries a small vertical frame along the edge FG of the vessel. Along this frame are stretched two fine parallel wires, whose images can be seen by reflection from the surface of the fluid, by an eye on the side PQ of the vessel, aided by a microscope with a distant focus. When the image of these wires is seen by reflection from any part of the fluid surface without the circle CD, it will suffer no change of form; but when it is seen by reflection from any portion of the elevated portion CD, the fibres will appear disturbed, and will indicate, by their return to the rectilineal form of accurate parallelism, the apparent termination of the circle CD. The same observation is made on the other side of A, at the boundary D, and a measure is thus obtained of the diameter of the circle CD, by means of the micrometer screw, by which the microscope on the side PQ, and the wire frame on the side FG are moved (being fixed to the same frame) along the sides of the vessel. In this way solids of all kinds may be used, and their exterior or acting surfaces may be easily cleared from grease and other adhering substances.

Fig. 41.



This apparatus may be improved by using two cylinders A,B in place of one, and by moving one of them, suppose B, from the other A till the two elevated circular portions CD,DE disturb the images of the wires, seen by reflexion from the intermediate point at D.

The motion of water in capillary tubes accelerated by electricity and by heat.

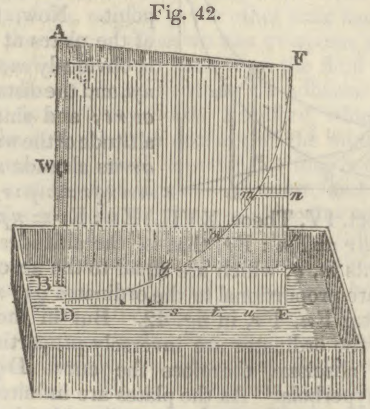
148. When water is made to pass through a capillary tube of such a bore that the fluid is discharged only by successive drops; the tube, when electrified, will furnish a constant and accelerated stream, and the acceleration is proportional to the smallness of the bore. A similar effect may be produced by employing warm water. Sir John Leslie found that a jet of warm water rose to a much greater height than a jet of cold water, though the water in both cases moved through the same aperture, and was influenced by the same pressure. A syphon also, which discharged cold water only by drops, furnished warm water in an uninterrupted stream.

Capillary Attraction, &c.

On the ascent of fluids between two inclined plates of glass.

149. Such are the leading phenomena of capillary tubes. The rise of fluids between two plates of glass remains to be considered; and while it furnishes us with a very beautiful experiment, it confirms the reasoning by which we have accounted for the elevation of fluids in cylindrical canals. Let ABEF and CDEF be two places of plate glass with

Fig. 42.



smooth and clean surfaces, having their sides EF joined together with wax, and their sides AB, CD kept a little distance by another piece of wax W, so that their interior surfaces, whose common intersection is the line EF, may form a small angle. When this apparatus is immersed in a vessel MN full of water, the fluid will rise in such a manner between the glass planes as to form the curve DqomF, which represents the surface of the elevated water. By measuring the ordinates mn, op, &c. of this curve, and also its abscissæ Fn, Fp, &c. Mr Hawksbee found it to be the common Apollonian hyperbola, having for its assymptotes the surface DE of the fluid, and EF the common intersection of the two planes. The following are the results which he obtained when the inclination of the planes was 20′:—

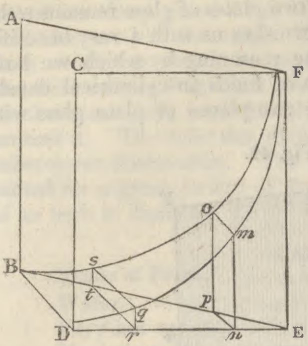
Experiments of Hawksbee.

Distances from the touching ends of the planes.	Heights of the water at the preceding distances.
13 inches	1
9	2
7	3
6	3¾
5	5
4	6¾
3	9
2½	12
2	15½
1¾	18
1½	21½
1¼	27½
1	35
¾	50
½	76

By repeating these observations at inclinations of 40′, and at various other angles, Mr Hawksbee found that the curve was an exact hyperbola in all directions of the planes. To the very same conclusion we are led by the principles already laid down; for as the distance between the plates diminishes at every point of the curve DqomF from D towards F, the water ought to rise higher at o than at q, still higher at m, and highest of all at F, where the distance between the plates is a minimum. To illustrate this more clearly, let ABEF and CDEF (fig. 43.) be the same plates of glass (inclined at a greater angle for the sake of distinctness), and let FmqD, and FosB be the curves which bound the surface of the elevated fluid. Then, since the altitudes of the water in capillary tubes are in-

Capillary Attraction, &c.

Fig. 43.



versely as their diameters, or the distances of their opposite sides, the altitudes of the water between two glass plates, should at any given point be inversely as the distances of the plates at that point. Now, the distance of the plates at the point m is obviously mo, or its equal np, and the distance at q is qs or rt; and since mn is the altitude of the water at m, and qr its altitude at q, we have $mn:qr=np:rt$; but (GEOMETRY, Sect. IV. Theor. XVII.) $En:Er=np:rt$; therefore $mn:qr=Fn:Fr$, that is, the altitudes of the fluid at the points m, q, which are equal to the abscissæ Fn, Fr (fig. 42.) are proportional to the ordinates qr, mn, equal to the abscissæ Fn, Fr, in fig. 42. But in the Apollonian hyperbola the ordinates are inversely proportional to their respective abscissæ, therefore the curve $DqmF$ is the common hyperbola. As the plates are infinitely near each other at the apex F, the water will evidently rise to that point, whatever be the height of the plates.

Ascent of fluids between parallel plates.

150. Mr Hawksbee extended his experiments to plates of glass placed parallel to each other, and separated to different distances, and he obtained the following results:—

Distance of plates.	Height of Ascent.	Constant quantity.
0.0625 of an inch.	0.166 of an inch.	0.0104
0.03125 ...	0.333 ...	0.0104
0.015625 ...	0.666 ...	0.0104
0.007802 ...	1.333 ...	0.0104

The following experiments on the same subject have been more recently made by M. Monge, MM. Haüy and Tremery, and M. Gay-Lussac.

In those made by M. Monge, the plates were first cleaned with caustic alkali, and well washed. Their degree of separation was ascertained by silver wires of different thicknesses, and the fluid used was the filtered water of the Seine. The following were the results:—

Distance of plates in parts of a line.	Height of ascent.	Constant quantity.
$\frac{4}{33}$ or 0.0101 inch.	15.5 lines.	0.1565
$\frac{4}{49}$ 0.0068	33.5	0.2278
$\frac{1}{28}$ 0.0030	74	0.222

The following result was obtained by MM. Haüy and Tremery:—

Distance of plate.	Height of ascent.	Const. quan.
1 millimètre.	6.5 millimètre.	6.5

The following measures were obtained by M. Gay-Lussac, with plates of glass ground perfectly flat:—

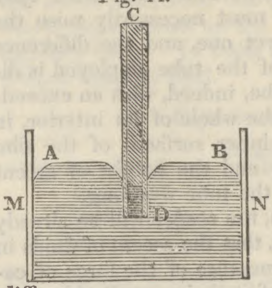
Distance of plates.	Height of Ascent above lowest point of concavity.	Temp. centig.
1.069 millimètre.	13.574	16°

Here the constant quantity is 14,51, or 0.02251, when reduced to English inches for a distance of $\frac{1}{100}$th of an inch.

151. The phenomena which we have been considering are all referrible to one simple fact, that the particles of glass have a stronger attraction for the particles of water than the particles of water have for each other. This is the case with almost all other fluids except mercury, the particles of which have a stronger attraction for each other than for glass. When capillary tubes, therefore, are plunged in this fluid, a new series of phenomena present themselves to our consideration. Let MN (fig. 44) be a vessel full of

Mercury descends in capillary tubes.

Fig. 44.



mercury. Plunge into the fluid the capillary tube CD; and the mercury, instead of rising in the tube, will remain stationary at E, its depression below the level surface AB being inversely proportional to the diameter of the bore. This was formerly ascribed to a repulsive force supposed to exist between mercury and glass, but we shall presently see that it is owing to a very different cause.

Capillary Attraction, &c.

152. That the particles of mercury have a very strong attraction for each other, appears from the globular form which a small portion of that fluid assumes, and from the resistance which it opposes to any separation of its parts. If a quantity of mercury is separated into a number of minute parts, all these parts will be spherical; and if two of these spheres be brought into contact, they will instantly rush together, and form a single drop of the same form. There is also a very small degree of attraction existing between glass and mercury; for a globule of the latter very readily adheres to the lower surface of a plate of glass. Now, suppose a drop of water laid upon a surface anointed with grease, to prevent the attraction of cohesion from reducing it to a film of fluid, this drop, if very small, will be spherical. If its size is considerable, the gravity of its parts will make it spheroidal, and as the drop increases in magnitude, it will become more and more flattened at its poles, like AB in fig. 45. The drop, however, will still retain its convexity at the circumference, however oblate be the spheroid into which it is moulded by the force of gravity. Let two pieces of glass oAm, pBn, be now brought in contact with the circumference of the drop; the mutual attraction between the particles of water which enabled it to preserve the convexity of its circumference, will yield to their superior attraction for glass; the space m, n, o, p, will be immediately filled; and the water will rise on the sides of the glass, and the drop will have the appearance of AB in fig. 46. If the drop AB (fig. 45.) be now supposed mercury instead of water, it will also, by the gravity of its parts, assume the form of an oblate spheroid; but when the pieces of glass oAm, pBn are brought close to its periphery, their attractive force upon the mercurial particles is not sufficient to counteract the mutual attraction of these particles; the mercury, therefore, retains its convexity at the circumference, and assumes the form exhibited in fig. 47. The small spaces op being filled by the pressure of the superincumbent fluid, while the spaces below m, n, still remain between the glass and the mercury. Now if the two plates of glass A, B be made to approach each other, the depressions m, n will still continue, and when the distance of the plates is so small that these depressions or indentations meet, the mercury will sink between the plates, and its descent will continue as the pieces of glass approach. Hence the depression of the mercury in capillary tubes becomes very intelligible. If two glass planes forming a small angle, as in fig. 42, be immersed in a vessel of mercury, the fluid will sink below the surface of the mercury in the vessel, and form an Apollonian hyperbola like DoF, having for its asymptotes the common intersection of the planes and the surface of mercury in the vessel.

Fig. 45.

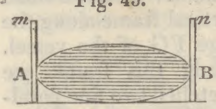


Fig. 46.

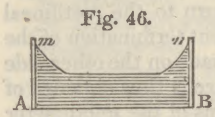

Fig. 47.

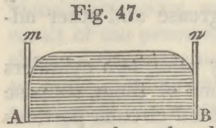

Mercury has a stronger attraction for its own particles than for glass.

Cause of the depression of mercury in capillary tubes.

153. The depression of mercury in capillary tubes is evidently owing to the greater attraction that subsists be-

tween the particles of mercury and those of glass. The difference between these two attractions, however, arises from an imperfect contact between the mercury and the capillary tube, occasioned by the interposition of a thin coating of water which generally lines the interior surface of the tube, and weakens the mutual action of the glass and mercury; for this action always increases as the thickness of the interposed film is diminished by boiling. In the experiments which were made by Laplace and Lavoisier on barometers, by boiling the mercury in them for a long time, the convexity of the interior surface of the mercury was often made to disappear. They even succeeded in rendering it concave, but could always restore the convexity by introducing a drop of water into the tube. When the ebullition of the mercury is sufficiently strong to expel all foreign particles, it often rises to the level of the surrounding fluid, and the depression is even converted into an elevation.

he depression of ercury in ass tubes, ultimately owing to imperfect contact between the lid and e fluid.

154. Between mercury and water there is likely to be some fluid in which the attraction of the glass for its particles is nearly equal to half the attraction of the fluid for itself. Sir David Brewster has observed that iodine dissolved in chloride of sulphur approximates to this condition; but not having the chloride by itself, he could not observe whether or not the effect is produced or influenced by the iodine. If it is, then a solution may be obtained, in which the above condition is perfect. The solution of the iodine already mentioned scarcely rises on the sides of the glass ball which contains it. (See 162.)

chard's xperiments on ne force ecessary raise the rface of solid om the rface of ater.

155. As most philosophers seem to agree in thinking that all the capillary phenomena are referable to the cohesive attraction of the superficial particles only of the fluid, a variety of experiments has been made in order to determine the force required to raise a horizontal solid surface from the surface of a fluid. Mr Achard found that a disc of glass, $1\frac{1}{2}$ French inches in diameter, required a weight of 91 French grains to raise it from the surface of the water at 69° of Fahrenheit, which is only 37 English grains for each square inch. At $44\frac{1}{2}$ of Fahrenheit the force was $\frac{1}{14}$ greater, or $39\frac{1}{2}$ grains, the difference being $\frac{1}{143}$ for each degree of Fahrenheit. From these experiments Dr Young concludes that the height of ascent in a tube of a given bore, which varies in the duplicate ratio of the height of adhesion, is diminished about $\frac{1}{180}$ for every degree of Fahrenheit that the temperature is raised above 50°; and he conjectures that there must have been some considerable source of error in Achard's experiments, as he never found this diminution to exceed $\frac{1}{1000}$. According to the experiments of Dutour, the force necessary to elevate the solid, or the quantity of water raised, is equal to 44.1 grains for every square inch.

Iorveau's xperiments on ne force ecessary raise etals om the rface of ercury.

156. According to the experiments of Morveau, the force necessary to elevate a circular inch of gold from the surface of mercury is 446 grains; a circular inch of silver, 429 grains; a circular inch of tin, 418 grains; a circular inch of lead, 397 grains; a circular inch of bismuth, 372 grains; a circular inch of zinc, 204 grains; a circular inch of copper, 142 grains; a circular inch of metallic antimony, 126; a circular inch of iron, 115 grains; and a similar surface of cobalt required 8 grains. The order in which these metals are arranged is the very order in which they are most easily amalgamated with mercury.

ay-Lussac's.

The most recent experiments on the adhesion of surfaces to fluids have been made by M. Gay-Lussac, who obtained the following results with a circular plate of glass 118.366 millimetres in diameter:—

Names of fluids.	Weight necessary to raise the plate from the glass.	Specific gravity.
Water, . .	59.40 grammes.	1.000
Alcohol, . .	31.08 ...	0.8196
Alcohol, . .	32.87 ...	0.8595
Oil of turpentine,	37.152 ...	0.9415

With a copper disc, 116.604 millimetres in diameter, the weight necessary to raise it from water, at the temperature of 18°.5 centigrade, was 57.945 grammes, differing very little, if at all, from glass, for the diminution of weight may be explained by the circumstance of the copper disc being nearly *two* millimeters less in diameter than the glass. In these experiments the discs were suspended from the scale of a balance, and the weights in the other scale successively increased till the force of adhesion was overcome at the instant when the disc detached itself from the fluid surface.

Experiments of Count Rumford on the adhesion of fluids.

157. A number of experiments on the adhesion of fluids have been lately made by Count Rumford, which authorize him to conclude, that on account of the mutual adhesion of the particles of fluid, a pellicle or film is formed at the superior and inferior surfaces of water, and that the force of the film to resist the descent of bodies specifically heavier than the fluid increases with the viscidity of the water. He poured a stratum of sulphuric ether upon a quantity of water, and introduced a variety of bodies specifically heavier than water into this compound fluid. A sewing needle, granulated tin, and small globules of mercury, descended through the ether, but floated upon the surface of the water. When the eye was placed below the level of the aqueous surface, the floating body, which was a spherule of mercury, seemed suspended in a kind of bag a little below the surface. When a larger spherule of mercury was employed, about the 40th or 50th of an inch in diameter, it broke the pellicle and descended to the bottom. The same results were obtained by using essential oil of turpentine or oil of olives instead of ether. When a stratum of alcohol was incumbent upon the water, a quantity of very fine powder of tin thrown upon its surface, descended to the very bottom, without seeming to have met with any resistance from the film at the surface of the water. This unexpected result Count Rumford endeavours to explain by supposing that the aqueous film was destroyed by the chemical action of the alcohol. In order to ascertain with greater accuracy the existence of a pellicle at the surface of the water, Count Rumford employed a cylindrical glass vessel 10 inches high and $1\frac{1}{2}$ inch in diameter, and filled it with water and ether as before. A number of small bodies thrown into the vessel descended through the ether and floated on the surface of the water. When the whole was perfectly tranquil, he turned the cylinder three or four times round with considerable rapidity in a vertical position. The floating bodies turned round along with the glass, and stopped when it was stopped; but the liquid water below the surface did not at first begin to turn along with the glass; and its motion of rotation did not cease with the motion of the vessel. From this Count Rumford concludes that there was a real pellicle at the surface of the water, and that this pellicle was strongly attached to the sides of the glass, so as to move along with it. When this pellicle was touched by the point of a needle, all the small bodies upon its surface trembled at the same time. The apparatus was allowed to stand till the ether had entirely evaporated, and when the pellicle was examined with a magnifier, it was in the same state as formerly; and the floating bodies had the same relative positions.

In order to shew that a pellicle was formed at the inferior surface of water, Count Rumford poured water upon mercury, and upon that a stratum of ether. He threw into the vessel a spherule of mercury about one-third of a line in diameter, which being too heavy to be supported by the pellicle at the superior surface of the water, broke it, and descending through that fluid, was stopped at its inferior surface. When this spherule was moved, and even compressed with a feather, it still preserved its spherical form, and refused to mix with the mass of mercury. When the viscidity of the water was increased by the infusion of gum-arabic, much larger spherules were supported by the

Capillary Attraction, &c.

pellicle. From the very rapid evaporation of ether, and its inability to support the lightest particles of a solid upon its surface, Count Rumford very justly concludes, that the mutual adhesion of its particles is very small.

Apparent attraction of floating bodies.

158. The approach of two floating bodies has been ascribed by some to their mutual attraction, and by others to the attraction of the portions of fluid that are raised round each by the attraction of cohesion. Dr Young, however, observes, that the approach of the two floating bodies is produced by the excess of the atmospheric pressure on the remote sides of the solids, above its pressure on their neighbouring sides; or, if the experiments are performed in a vacuum, by the equivalent hydrostatic pressure or suction derived from the weight and immediate cohesion of the intervening fluid. This force varies alternately in the inverse ratio of the square of the distance; for when the two bodies approach each other, the altitude of the fluid between them is increased in the simple inverse ratio of the distance; and the mean action, or the negative pressure of the fluid on each particle of the surface, is also increased in the same ratio. When the floating bodies are surrounded by a depression, the same law prevails, and its demonstration is still more simple and obvious.

Theory of Dr Young.

Of Monge.

159. A different view of the subject has been given by Monge, who made a number of accurate experiments on the subject, and deduced from them the following laws:—

1. If two floating bodies, capable of being wetted with the fluid on which they float, are placed near each other, they will approach as if mutually attracted.

In order to explain this law, let AB, CD (fig. 48.) be two suspended plates of glass, placed at such distance that the

Fig. 48.

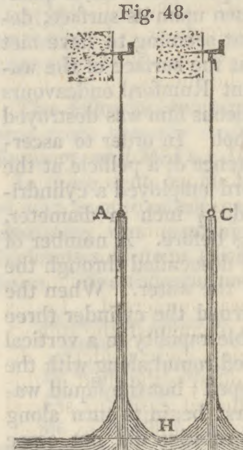

Fig. 49.

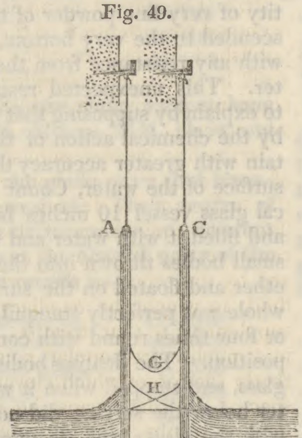
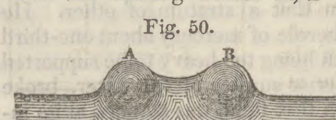


point H where the two portions of elevated fluid meet, is on a level with the rest of the water, the two plates will remain stationary and in perfect equilibrium. But if they are brought nearer one another, as in fig. 49, the water will rise between them to a point H above the level, and by a nearer approximation, to the point G. The water thus elevated, acting like a curved chain hung to the two plates, attracts the sides of the plates, and brings them together in a horizontal direction. The very same thing takes place with the floating bodies A, B placed at such a distance that the water rises between them above its level, and hence these bodies will approach by the attraction of the fluid on their inner sides.

Fig. 50.



2. When the two floating bodies A, B, are not capable of being wetted, they will approach each other as if mutually attracted, when they are placed near one another.

Fig. 51.

In this case the fluid is depressed between them below its natural level H, and the two bodies are pressed *inwards* or towards each other, which pressure being greater than the pressure *outwards* of the fluid between them, they will approach each other by the action of the difference of these pressures.

3. If one of the bodies A, is capable of being wetted, and the other B not, as shewn in the figure, they will recede from each other as if mutually repelled.

Fig. 52.

As the fluid rises round A, and is depressed round B, the depression round B will not be equal all round, and hence the body B, being placed as if on an inclined plane, it will move to the right hand when the pressure is the least.

In this last case, La Place was led by theory to believe that when B is placed very near A, the repulsion will be converted into attraction. M. Haüy tried this experiment with planes of ivory and talc, the former being incapable of being wetted with water and the latter not; and he found, in conformity with La Place's prediction, that at a certain short distance the talc moved suddenly into contact with the ivory.

Phenomena of lighted wicks and camphor.

160. The phenomena of attraction and repulsion exhibited between small lighted wicks, swimming in a basin of oil, and the motions of floating evaporable substances like camphor, and also of potassium and light substances, such as cork, impregnated with ether, have been sometimes treated under this head. The first of these classes of phenomena arise from an unbalanced pressure upon the floating wick, arising from a difference of temperature of different parts of the oil, and the movements of the second class arise from the reaction of the currents of vapour which flow from the floating substances. A full account of these phenomena will be found in the *Edinburgh Transactions* (vol. iv. p. 44), in the *Mémoires Presentées à L'Institut* (tom. i. p. 125), and the more recent observations of Matteucci, in the *Annales de Chimie* (June 1833, tom. liii. p. 216–219.)

Theory of Capillary Attraction.

Theory of capillary attraction Fig. 53.

161. Clairaut was the first mathematician who attempted to analyze the forces which contribute to the ascent of fluids in capillary tubes.[1] After pointing out the insufficiency of preceding theories, he gives an analysis of the different forces which contribute to the suspension of fluids in capillary tubes.

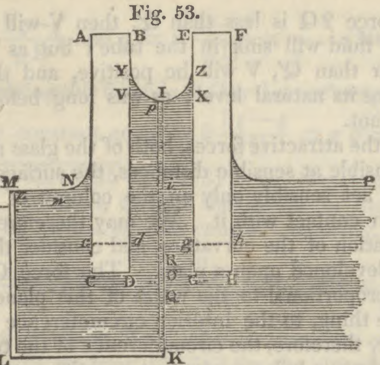
Let ABCDEFGH (fig. 53.) be the section of a capillary tube, MNP the surface of the water in the vessel, I*i* the height of its ascent, viz. the concave surface of the fluid column, and IKLM an indefinitely small column of fluid reaching to the surface at M. Now the column ML is solicited by the force of gravity which acts through the whole extent of the column, and by the reciprocal attraction of the moleculæ, which, though they act the same in all the points of the column, only exhibit their effects towards the extremity M. If any particle *e* is taken at a less distance from the surface than the distance at which the attraction of the liquid generally terminates, and if *mn* is a plane parallel to MN, and at the same distance from the particle *e*,

[1] *Théorie de la Figure de la Terre*, chap. x. Paris, 1743, 1808.

Capillary Attraction, &c.

then this particle will be equally attracted by the water be-

Fig. 53.



tween the planes MN, *mn*. The water, however, below *mn*, will attract the particle downwards, and this effect will take place as far as the distance where the attraction ceases.

The column IK, on the other hand, which is in a state of equilibrium with ML, is acted upon by the force of gravity through the whole extent of the column, also by other forces at the upper and lower extremities of the tube. The forces exerted at the upper part of the column are, the attraction of the tube upon the particles of water, and the reciprocal attraction of these particles; but as every particle is as much drawn upwards as downwards by the first of these forces, the consideration of it may be dropped. In order to estimate the other force, let a horizontal plane VX touch the concavity at I, a particle p, situated infinitely near to I, is attracted by all the particles above VX, and by all below it whose sphere of activity comprehends that particle; and as the particles above p are fewer than those below it, the result of these forces must be a force acting downwards.

In order to estimate the value of the forces which act at the lower end O of the tube, let us suppose that the tube has a prolongation to the bottom of the vessel, formed of matter of the same density as the water. Let a particle R be situated a little above the extremity of the tube, and another Q as much below that extremity, they will be equally acted upon by the water above that place, and by the water between the fictitious prolongation of the tube, and therefore these forces will destroy one another.

By applying to the case of the particle R the same reasoning that was used for the particle e, it will appear that the result of its attraction by the tube is an attraction upwards. The particle R is likewise attracted downwards by the supposed prolongation of the tube, and the difference between these is the real effect. The other particle Q is also drawn upwards by the tube with the same force as R, since, by the hypothesis, it is as far distant from the points D, G, as the particle R is from the points d, g, where, with respect to it, the real attraction of the tube commences. The particle Q is attracted also downwards, by the supposed prolongation of the tube, and the difference of these actions is the real effect. Hence the double of this force is the sum of all the forces that act at the lower part of the tube. These forces, when combined with those exerted at the top of the tube, and with the force of gravity, give the total expression, which should be combined with that of the forces with which the column ML is actuated.

The formula obtained by Clairaut for the altitude I i, fig. 53, is

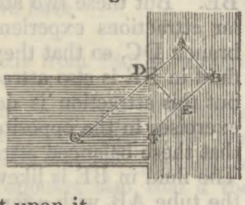
$$\mathrm{I}\,i = \frac{(2Q - Q').\int dx\,[b, x] + \int dx\left[b,\ x,\ Q,\ Q'\right]}{p}$$

in which Q is the intensity of the attraction of the glass, Q′ the intensity of the attraction of the water, b the interior radius of the tube, and p the force of gravity.

Clairaut then observes, that there is an infinitude of possible laws of attraction which will give a sensible quantity for the elevation of the fluid I i above the level MN, when the diameter of the tube is very small, and a quantity next to nothing when the diameter is considerable; and he remarks, that we may select the law which gives the inverse ratio between the diameter of the tube and the height of the liquid, conformable to experiment.

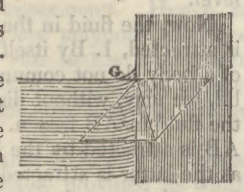
162. It follows from the preceding formula, that if any solid AB possesses half the attracting power of the fluid CD, the surface of the fluid will remain horizontal; for the attraction being represented by DA, DE, and DC, DA and DE may be combined into DB, and DB and DC into DE, which is vertical. The water will therefore not be raised, since the surface of a fluid at rest must be perpendicular to the resulting direction of all the forces which act upon it.

Fig. 54.



When the attracting power of the solid is more than half as great, the resultant of the forces will be GF in fig. 55, and therefore the fluid must rise towards the solid, in order to be perpendicular to GF. When the attractive power of the solid is less than that of the fluid, the resultant will be HF in fig. 55; and therefore, as in the case of mercury, the surface must be depressed, in order to be perpendicular to the force.

Fig. 55.



163. The subject of capillary attraction has more recently occupied the attention of the late Marquis de la Place, who published his first remarks on the subject in 1806. In 1807 he published a supplement to his theory, in which he compares his formula with the experiments of Gay-Lussac and others.

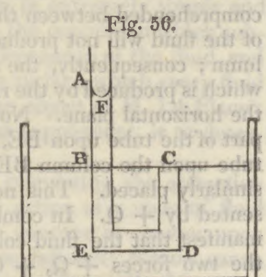
Account of La Place's Theory.

In the first treatise published by M. La Place, his method of considering the phenomena was founded on the form of the surface of the fluid in capillary spaces, and on the conditions of equilibrium of this fluid in an infinitely narrow canal, resting by one of its extremities upon this surface, and by the other on the horizontal surfaces of an indefinite fluid, in which the capillary tube was immersed. In his supplement to that treatise, he has examined the subject in a much more popular point of view, by considering directly the forces which elevate and depress the fluid in this space. By this means, he is conducted easily to several general results, which it would have been difficult to obtain directly by his former method. Of this method we shall endeavour to give as clear a view as possible.

Analysis of the capillary forces.

164. Let AB, fig. 56, be a vertical tube whose sides are perpendicular to its base, and which is immersed in a fluid that rises in the interior of the tube above its natural level. A thin film of fluid is first raised by the action of the sides of the tube; this film raises a second film, and this second film a third film, till the weight of the volume of fluid raised exactly balances all the forces by which it is actuated. Hence it is obvious, that the elevation of the column is produced by the attraction of the tube upon the fluid, and the attraction of the fluid for itself. Let us suppose that the inner surface of the tube AB is prolonged to E, and after bending itself horizontally in the direction ED, that it assumes a vertical direction DC; and let us suppose the sides of this tube to be so extremely thin, or to be

Fig. 56.



Capillary Attraction, &c.

formed of a film of ice, so as to have no action on the fluid which it contains, and not to prevent the reciprocal action which takes place between the particles of the first tube AB and the particles of the fluid. Now, since the fluid in the tubes AE, CD, is in equilibrio, it is obvious that the excess of pressure of the fluid in AE is destroyed by the vertical attraction of the tube and of the fluid upon the fluid contained in AB. In analyzing these different attractions, La Place considered first those which take place under the tube AB. The fluid column BE is attracted, 1. by itself; 2. by the fluid surrounding the tube BE. But these two attractions are destroyed by the similar attractions experienced by the fluid contained in the branch DC, so that they may be entirely neglected. The fluid in BE is also attracted vertically by the fluid in AB; but this attraction is destroyed by the attraction which it exercises in the opposite direction upon the fluid in BE, so that these balanced attractions may likewise be neglected. The fluid in BE is likewise attracted vertically upwards by the tube AB, with a force which we shall call Q, and which contributes to destroy the excess of pressure exerted upon it by the column BF raised in the tube above its natural level.

Now, the fluid in the lower part of the round tube AB is attracted, 1. By itself; but as the reciprocal attractions of a body do not communicate to it any motion if it is solid, we may, without disturbing the equilibrium, conceive the fluid in AB frozen. 2. The fluid in the lower part of AB is attracted by the interior fluid of the tube BE, but as the latter is attracted upwards by the same force, these two actions may be neglected as balancing each other. 3. The fluid in the lower part of BE is attracted by the fluid which surrounds the ideal tube BE, and the result of this attraction is a vertical force acting downwards, which we may call $-Q'$, the contrary sign being applied, as the force is here opposite to the other force Q. As it is highly probable that the attractive forces exercised by the glass and the water vary according to the same function of the distance, so as to differ only in their intensities, we may employ the constant co-efficients ϱ, ϱ' as measures of their intensity, so that the forces Q and $-Q'$ will be proportional to ϱ, ϱ'; for the interior surface of the fluid which surrounds the tube BE, is the same as the interior surface of the tube AB. Consequently, the two masses, viz. the glass in AB, and the fluid round BE differ only in their thickness; but as the attraction of both these masses is insensible at sensible distances, the difference of their thicknesses, provided their thicknesses be sensible, will produce no difference in the attractions. 4. The fluid in the tube AB is also acted upon by another force, namely, by the sides of the tube AB in which it is inclosed. If we conceive the column FB divided into an infinite number of elementary vertical columns, and if at the upper extremity of one of these columns we draw a horizontal plane, the portion of the tube comprehended between the plane and the level surface BC of the fluid will not produce any vertical force upon the column; consequently, the only active vertical force is that which is produced by the ring of the tube immediately above the horizontal plane. Now, the vertical attraction of this part of the tube upon BE, will be equal to that of the entire tube upon the column BE, which is equal in diameter, and similarly placed. This new force will therefore be represented by $+Q$. In combining these different forces, it is manifest that the fluid column BF is attracted upwards by the two forces $+Q$, $+Q$, and downwards by the force $-Q'$; consequently the force with which it is raised upwards will be $2Q-Q'$. If we represent by V the volume of the column BE, by D its intensity, and by g the force of gravity, then gDV will represent the weight of the elevated column; but as this weight is in equilibrio with the forces by which it is elevated, we have the following equation:

$$gDV = 2Q - Q'.$$

If the force $2Q$ is less than Q', then V will be negative, and the fluid will sink in the tube; but as long as $2Q$ is greater than Q', V will be positive, and the fluid will rise above its natural level; as was long before shewn by M. Clairaut.

Since the attractive forces, both of the glass and the fluid, are insensible at sensible distances, the surface of the tube AB will act sensibly only on the column of fluid immediately in contact with it. We may therefore neglect the consideration of the curvature, and consider the inner surface as developed upon a plane. The force Q will therefore be proportional to the width of this plane, or what is the same thing, to the interior circumference of the tube. Calling c, therefore, the circumference of the tube, we shall have $Q = \varrho c$; ϱ being a constant quantity, representing the intensity of the attraction of the tube AB upon the fluid, in the case where the attractions of different bodies are expressed by the same function of the distance. In every case, however, ϱ expresses a quantity dependent on the attraction of the matter of the tube, and independent of its figure and magnitude. In like manner we shall have $Q' = \varrho' c$; ϱ' expressing the same thing with regard to the attraction of the fluid for itself, that ϱ expressed with regard to the attraction of the tube for the fluid. By substituting these values of Q Q', in the preceding equation, we have

$$gDV = c(2\varrho - \varrho').$$

If we now substitute, in this general formula, the value of c in terms of the radius if it is a capillary tube, or in terms of the sides if the section is a rectangle, and the value of V in terms of the radius and altitude of the fluid column, we shall obtain an equation by which the heights of ascent may be calculated for tubes of all diameters, after the height, belonging to any given diameter, has been ascertained by direct experiment.

Application of the formula to cylindrical tubes;

165. In the case of a cylindrical tube, let π represent the ratio of the circumference to the diameter, h the height of the fluid column reckoned from the lower point of the meniscus, q the mean height to which the fluid rises, or the height at which the fluid would stand if the meniscus were to fall down and assume a level surface, then we have πr^3 for the solid contents of a cylinder of the same height and radius as the meniscus, and as the meniscus, added to the solid contents of the hemisphere of the same radius, must be equal to πr^2, we have $\pi r^3 - \frac{2\pi r^3}{3}$, or $\frac{\pi r^3}{3}$, for the solid contents of the meniscus. But since $\frac{\pi r^3}{3} = \pi r^2 \times \frac{r}{3}$, it follows that the meniscus $\frac{\pi r^3}{3}$ is equal to a cylinder whose base is πr^2, and altitude $\frac{r}{3}$. Hence, we have

$$q = h + \frac{r}{3};$$

or what is the same thing, the mean altitude q in a cylinder is always equal to the altitude h of the lower point of the concavity of the meniscus increased by one-third of the radius, or one-sixth of the diameter of the capillary tube. Now, since the contour c of the tube $= 2\pi\varrho$, and since the volume V of water raised is equal to $q \times \pi r^2$, we have, by substituting these values in the general formula,

$$gDq\pi r^2 = 2\pi r(2\varrho - \varrho'), \quad \text{(No 1.)}$$

apillary traction, &c.

and dividing by πr and g D, we have,

$$r\,q = 2\,\frac{2\varrho-\varrho'}{g\text{D}} \text{ and } q = 2\,\frac{2\varrho-\varrho'}{g\text{D}} \times \frac{1}{r}. \quad \text{(No. 2.)}$$

plica- n of the mula Gay- ussac's peri- nts on ter;

166. In applying this formula to Gay-Lussac's experiments, we have the constant quantity $2\,\frac{2\varrho-\varrho}{g\text{D}} = r\,q = \overline{647205 \times 23,1634 + 0,215735} = 15,1311$ for Gay-Lussac's 1st experiment. In order to find the height of the fluid in his 2d tube by means of this constant quantity, we have

$$r = \frac{1.90381}{2} = 0.951905, \text{ and } 2\,\frac{2\varrho-\varrho'}{g\text{D}} \times \frac{1}{3} = q = \frac{15,1311}{0.951095}$$

$= 15.8956$, from which, if we subtract one-sixth of the diameter, or 0.3173, we have 15.5783 for the altitude h of the lower point of the concavity of the meniscus, which differs only 0.0078 from 15.861 the observed altitude.

Gay- ussac's peri- nts on ohol;

If we apply the same formula to Gay-Lussac's experiments on alcohol, we shall find the constant quantity $2\,\frac{2\varrho-\varrho'}{g\text{D}} = 6.0825$ as deduced from the 1st experiment, and $h = 6.0725$, which differs only 0.0100 from 6.08397, the altitude observed.

From these comparisons, it is obvious that the mean altitudes, or the values of q, are very nearly reciprocally proportional to the diameters of the tubes; for, in the experiments on water, the value of q deduced from this ratio is 15.895, which differs little from 15.9034, the value found from experiment; and that, in accurate experiments, the correction made by the addition of the sixth part of the diameter of the tube is indispensably requisite.

rectan- ar ca- lary ces.

167. If the section of the pipe in which the fluid ascends is a rectangle, whose greater side is a, and its lesser side d, then the base of the elevated column will be $= a\,d$, and its perimeter $c = 2\,a + 2\,d$. Hence, the value of the meniscus will be $\frac{a\,d^2}{2} - \frac{a\,\pi\,d^2}{8} = \frac{a\,d^2}{2}\left(1 - \frac{\pi}{4}\right)$, that is $q = h + \frac{d}{2}\left(1 - \frac{\pi}{4}\right)$. Hence, if in the general equation No. 1, we substitute for c its equal $2a + 2d$, and for V its equal adq, we have

$$g\text{D}\,q\,a\,d = \overline{2\varrho-\varrho'} \times \overline{2a+2d},$$

and dividing by a and by g D, we have

$$d\,q = 2\,\frac{2\varrho-\varrho'}{g\text{D}} \times 1 + \frac{d}{a}, \text{ and}$$

$$q = \frac{2\,\frac{2\varrho-\varrho'}{g\text{D}} \times 1 + \frac{d}{a}\,.}{d}$$

In applying this formula to the elevation of water between two glass plates, the side a is very great compared with d, and therefore the quantity $\frac{d}{a}$ being almost insensible, may be safely neglected. Hence the formula becomes

$$q = 2\,\frac{2\varrho-\varrho'}{g\text{D}} \times \frac{1}{d}.$$

By comparing this formula with the formula No. 2, it is obvious that water will rise to the same height between plates of glass as in a tube, provided the distance d between the two plates of glass is equal to r, or half the diameter of the tube. This result was obtained by Newton, and has been confirmed by the experiments of succeeding writers.

Capillary Attraction, &c.

Comparison of the formula with Gay-Lussac's experiments.

As the constant quantity $2\,\frac{2\varrho-\varrho'}{g\text{D}}$ is the same as already found for capillary tubes, we may take its value, viz. 15,1311, and substitute it in the preceding equation, we then have

$q = \frac{15.1311}{1.060}\,t = 14.1544$; and since

$h = q - \frac{d}{2}\left(1 - \frac{\pi}{2}\right)$, subtracting

$\frac{d}{2}\left(1 - \frac{\pi}{4}\right) = 0.1147$, we have

$h = 14.0397$, which differs very little from 13.574, the observed altitude.

It will be seen from the formula No. 2, that of all tubes that have a prismatic form, the hollow cylinder is the one in which the volume of fluid raised is the least possible, as it has the smallest perimeter. It appears, also, that if the section of the tube is a regular polygon, the altitudes of the fluid will be reciprocally proportional to the homologous lines of the similar base, a result which, as we have seen, M. Gellert obtained from direct experiment. Hence, in all prismatic tubes whose sections are polygons inscribed in the same circle, the fluid will rise to the same mean height. If one of the two bases is, for example, a square, and the other an equilateral triangle, the altitudes will be as $2 : 3\frac{3}{4}$, or very nearly as $7 : 8$.

Fluids may be in a state of stable and instable equilibrium in the same tube.

168. M. La Place has remarked, that there may be several states of equilibrium in the same tube, provided its width is not uniform. If we suppose two capillary tubes communicating with one another, so that the smallest is placed above the greatest, we may then conceive their diameters and lengths to be such, that the fluid is at first in equilibrium above its level in the widest tube, and that in pouring in some of the same fluid, so as to reach the smaller tube, and fill part of it, the fluid will still maintain itself in equilibrio. When the diameter of a capillary tube diminishes by insensible gradations, the different states of equilibrium are alternately stable and instable. At first the fluid tends to raise itself in the tube, and this tendency diminishing, becomes nothing in a state of equilibrium. Beyond this it becomes negative, and consequently the fluid tends to descend. Thus the first equilibrium is stable, since the fluid, being a little removed from this state, tends to return to it. In continuing to raise the fluid, its tendency to descend diminishes, and becomes nothing in the second state of equilibrium. Beyond this it becomes positive, and the fluid tends to rise, and consequently to remove from this state which is not stable. In a similar manner it will be seen, that the third state is stable, the fourth instable, and so on.

Connexion between the rise of fluids and the curvature of their surface.

169. Although the preceding method of considering the phenomena of capillary attraction is extremely simple and accurate, yet it does not indicate the connexion which subsists between the elevation and depression of the fluid, and the concavity or convexity of the surface which every fluid assumes in capillary spaces. The object of M. La Place's first method, contained in his first supplement, is to determine this connexion.

By means of the methods for calculating the attraction of spheroids, he determines the action of a mass of fluid terminated by a spherical surface, concave or convex, upon a column of fluid contained in an infinitely narrow canal, directed towards the centre of this surface. By this action La Place means the pressure which the fluid contained in the canal would exercise, in virtue of the attraction of its entire mass upon a plane base situated in the interior of the canal, and perpendicular to its sides, at any sensible distance from the surface, this base being taken for unity. He then shews that this action is smaller when the surface is concave than when it is plane, and greater when the surface is convex. The analytical expression of this action is composed of two terms. The first of these terms, which is much greater than the second, expresses the action of the mass terminated by a plane surface; and the second term expresses the part of the action due to the sphericity of the surface, or, in other words, the action of the meniscus comprehended between this surface and the plane which touches it. This action is either additive to the preceding, or subtractive from it, according as the surface is convex or concave. It is reciprocally proportional to the radius of the spherical surface; for the smaller that this radius is, the meniscus is the nearer to the point of contact.

From these results relative to bodies terminated by sensible segments of a spherical surface, La Place deduces this general theorem. "In all the laws which render the attraction insensible at sensible distances, the action of a body terminated by a curve surface upon an interior canal infinitely narrow, perpendicular to this surface in any point, is equal to the half sum of the actions upon the same canal of two spheres, which have for their radii the greatest and the smallest of the radii of the osculating circle of the surface at this point."

170. By means of this theorem, and the laws of hydrostatics, La Place has determined the figure which a mass of fluid ought to take when acted upon by gravity, or contained in a vessel of a given figure. The nature of the surface is expressed by an equation of partial differences of the second order, which cannot be integrated by any known method. If the figure of the surface is one of revolution, the equation is reduced to one of ordinary differences, and is capable of being integrated by approximation, when the surface is very small. La Place next shews, that a very narrow tube approaches the more to that of a spherical segment as the diameter of the tube becomes smaller. If these segments are similar in different tubes of the same substance, the radii of their surfaces will be inversely as the diameter of the tubes. This similarity of the spherical segments will appear evident, if we consider that the distance at which the action of the tube ceases to be sensible is imperceptible; so that if, by means of a very powerful microscope, this distance should be found equal to a millimetre, it is probable that the same magnifying power would give to the diameter of the tube an apparent diameter of several metres. The surface of the tube may therefore be considered as very nearly plane, in a radius equal to that of the sphere of sensible activity; the fluid in this interval will therefore descend, or rise from this surface, very nearly as if it were plane. Beyond this the fluid being subjected only to the action of gravity, and the mutual action of its own particles, the surface will be very nearly that of a spherical segment, of which the extreme planes being those of the fluid surface, at the limits of the sphere of the sensible activity of the tube, will be very nearly in different tubes equally inclined to their sides. Hence it follows that all the segments will be similar.

171. The approximation of these results gives the true cause of the ascent or descent of fluids in capillary tubes in the inverse ratio of their diameter. If in the axis of a glass tube we conceive a canal infinitely narrow, which bends

Fig. 56. round like the tube ABEDC in fig. 56, the action of the water in the tube in this narrow canal will be less, on account of the concavity of its surface, than the action of the water in the vessel on the same canal. The fluid will therefore rise in the tube to compensate for this difference of action; and as the concavity is inversely proportional to the diameter of the tube, the height of the fluid will be also inversely proportional to that diameter. If the surface of the interior fluid is convex, which is the case with mercury in a glass tube, the action of this fluid on the canal will be greater than that of the fluid in the vessel, and therefore the fluid will descend in the tube in the ratio of their difference, and consequently in the inverse ratio of the diameter of the tube.

In this manner of viewing the subject, the attraction of capillary tubes has no influence upon the ascent or depression of the fluids which they contain, but in determining the inclination of the first planes of the surface of the interior fluid extremely near the sides of the tube, and upon this inclination depends the concavity or convexity of the surface, and the length of its radius. The friction of the fluid against the sides of the tube may augment or diminish a little the curvature of its surface, of which we see frequent examples in the barometer. In this case the capillary effects will increase or diminish in the same ratio.

The differential equation of the surfaces of fluids inclosed in capillary spaces of revolution, conducts La Place to the following general result; that if into a cylindrical tube we introduce a cylinder which has the same axis as that of the tube, and which is such that the space comprehended between its surface and the interior surface of the tube has very little width, the fluid will rise in this space to the same height as in a tube whose radius is equal to this width. If we suppose the radii of the tube and of the cylinder infinite, we have the case of a tube included between two parallel and vertical planes, very near each other. This result has been confirmed, as we have already seen, by the experiments of Newton, Haüy, and Gay-Lussac. La Place then applies his theory to the phenomena presented by a drop of fluid, either in motion or suspended in equilibrio, either in a conical capillary tube, or between two plates, and inclined to each other, as discovered by Mr Hawksbee; to the mutual approximation of two parallel and vertical discs immersed in a fluid; to the phenomena which take place when two plates of glass are inclined to each other at a small angle; and to the determination of the figure of a large drop of mercury laid upon a horizontal plate of glass.

On the Form of Drops.

172. It was observed by M. Monge, that when drops of alcohol fall upon a surface of the same fluid, they do not at first mix with it, but roll over its surfaces with great facility, impinge against each other, and are reflected like billiard balls. M. Monge observed an analogous phenomenon in the drops of water which fall from the oars during the rowing of a boat, and during the condensation of the vapour of warm fluids.

In repeating the experiments of Monge, Sir David Brewster found that the phenomena were most beautiful when the capillary tube discharged the drops upon the inclined plane of fluid, which is elevated by the attraction of the edge of the cup. They ran down the inclined plane with great velocity, and sometimes even ascended the similar plane on the opposite side of the vessel. When the drop was discharged at the distance of one or two-tenths of an inch from the surface of the water, they had always the same magnitude when the tube was held in the same position; but when the point of the tube was brought within a tenth of an inch of the surface of the spirit of wine, this surface, instead of attracting the drop to it instantly, as Saussure would have predicted, actually resisted the gravity or weight of drop, and allowed it to attain a diameter nearly twice as great as it would have had, if it had been discharged in the ordinary manner. This swoln globule floated upon the surface in the same manner as the smaller drops, surrounded with a depression of the fluid surface similar to what is produced by a glass globule floating on mercury, or by the feet of particular insects, that have the power of running upon the surface of water. The floating

Capillary attraction, &c.

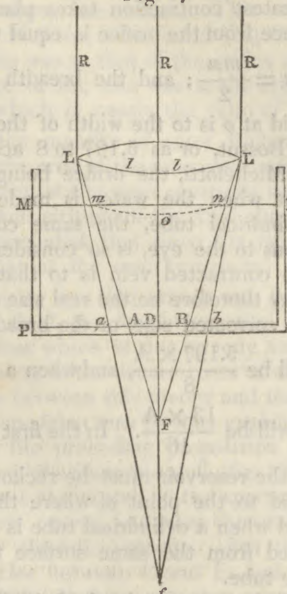
globules are often produced even when they are discharged from a height of three or four inches; and by letting them fall upon the inclined plane of fluid formerly mentioned, they will often rebound from the surface, and fall over the sides of the cup.

Opening in fluid film.

173. In a phenomenon the very reverse of the formation of a drop, which was first noticed by Sir David Brewster, the cohesion of fluids is shewn in a very interesting manner. If we take a phial, with a wide mouth, half filled with Canada balsam, and allow the balsam to flow to the mouth of the phial and fill it up, then when the phial is placed on its bottom, a fine transparent film of balsam will be seen extending over the mouth of the phial. If we now take a piece of slender wire, and touch the film near the middle, so as to tear away a little part of it, the remaining part of the film which has been elevated by this force will descend to its level position, and the ragged aperture from which the balsam has been torn will be seen to assume a form perfectly circular, having its edge in a slight degree thickened, like a circle with a raised margin turned out of a piece of wood. This fine circular aperture grows wider and wider, and continues to preserve its circular form till the mouth of the phial is again opened.

174. We shall now conclude the subject of capillary attraction with an account of an experiment made by Sir David Brewster, and intimately connected with the subject. Above a vessel MNOP, Fig. 57, nearly filled with water, a convex lens LL was placed at the distance of the 10th of an inch, and rays R, R, R, were incident upon its upper surface. The focus of these rays was at F, a little beyond the bottom of the vessel, so that a circular image of the luminous object was seen on the bottom of the vessel, having AB for its diameter. If the lens is now made to descend gradually towards the surface of the water, and the eye kept steadily upon the luminous image AB, a dark spot will be seen at D in the centre of AB, a little while before the lens attracts and elevates the water MN. Sometimes this spot may be seen playing backwards and forwards by the slight motion of the hand, so that the lens can even be withdrawn from the fluid surface without having actually touched it. In general, however, the sudden rise of the water to the lens follows the appearance of the black spot. When the water is in contact with the glass, the focus of the rays R, R, is now transferred to f, and the circular image on the bottom is now ab, and the intensity of the light in this circle is to that in the circle AB, as $AB^2 : ab^2$. Now it is obvious, that the darkish spot at D is just the commencement of the transference of the focus from F to f; or when the dark spot is produced, the progress of the rays is the same as if the focus were transferred to f. This remarkable effect may arise from two causes. 1. The approach of the lens to the surface MN, may occasion a depression mon in the surface of the fluid of the same curvature as LlL, which would have the effect of transferring the focus from F to f. 2. The transference of the focus from F to f may arise from the optical contact of the glass of water taking place at a greater distance from the lens than that at which capillary attraction commences.

Fig. 57.



PART II.—HYDRAULICS.

Definition.

175. Hydraulics is that branch of the science of Hydrodynamics which relates to fluids in motion. It comprehends the theory of running water, whether issuing from orifices in reservoirs by the pressure of the superincumbent mass, or rising perpendicularly in *jets d'eaux* from the pressure of the atmosphere; whether moving in pipes and canals, or rolling in the beds of rivers. It comprehends also the resistance or the percussion of fluids, and the oscillation of waves.

CHAPTER I.—THEORY OF FLUIDS ISSUING FROM ORIFICES IN RESERVOIRS, EITHER IN A LATERAL OR A VERTICAL DIRECTION.

Preliminary observations.

176. If water issues from an orifice either in the bottom or side of a reservoir, the surface of the fluid in the reservoir is always horizontal till it reaches within a little of the bottom. When a vessel, therefore, is emptying itself, the particles of the fluid descend in vertical lines, as is represented in fig. 58.; but when they have reached within three or four inches of the orifice mn, the particles which are not immediately above it change the direction of their motion, and make for the orifice in directions of different degrees of obliquity. The velocities of these particles may be decomposed into two others, one in a horizontal direction, by which they move parallel to the orifice, and the other in a vertical direction, by which they approach that orifice. Now, as the particles about C and D move with greater obliquity than those nearer E, their horizontal velocities must also be greater, and their vertical velocities less. But the particles near E move with so little obliquity that their vertical are much greater than their horizontal velocities, and very little less than their absolute ones. The different particles of the fluid, therefore, will rush through the orifice mn with very different velocities, and in various directions, and will arrive at a certain distance from the orifice in different times. On account of the mutual adhesion of the fluid particles, however, those which have the greatest velocity drag the rest along with them; and as the former move through the centre of the orifice, the breadth of the issuing column of fluid will be less at op than the width of the orifice mn.

Fig. 58.

Cause of the vena contracta

177. That the preceding phenomena really exist when a vessel of water is discharging its contents through an aperture, experience sufficiently testifies. If some small substances specifically heavier than water be thrown into the fluid when the vessel is emptying itself, they will at first descend vertically, and when they come within a few inches of the bottom they will deviate from this direction, and describe oblique curves similar to those in the figure.

Description of the vena contracta.

The contraction of the vein or column of fluid at op is also manifest from observation. It was first discovered by Sir Isaac Newton, and denominated the *vena contracta.* The greatest contraction takes place at a point o, whose distance from the orifice is equal to half its diameter, so that $om = \frac{mn}{2}$; and the breadth of the vein or column of fluid at o is to the width of the orifice as 5 to 8 according to Bossut, or as 5.197 to 8 according to the experiments of Michelotti, the orifice being perforated in a thin plate. But when the water is made to issue through a short cylindrical tube, the same contraction, though not obvious to the eye, is so considerable, that the diameter of the contracted vein is to that of the orifice as 6.5 to 8. If A therefore be the real size of the orifice in a thin plate, its corrected size, or the breadth of the contracted vein, will be $\frac{5.197 \times A}{8}$, and when a cylindrical tube is employed it will be $\frac{13 \times A}{16}$. In the first case the height of the water in the reservoir must be reckoned from the surface of the fluid to the point o, where the vein ceases to contract; and when a cylindrical tube is employed, it must be reckoned from the same surface to the exterior aperture of the tube.

Relation between the velocity of the fluid at the orifice, and that of the interior laminæ.

178. Suppose the fluid ABCD (fig. 58) divided into an infinite number of equal *strata* or *laminæ* by the horizontal surfaces MN, gh infinitely near each other; and let $mnop$ be a small column of fluid which issues from the orifice in the same time that the surface MN descends to gh. The column $mnop$ is evidently equal to the lamina MN gh, for the quantity of fluid which is discharged during the time that MN descends to gh, is evidently MN hg; and to the quantity discharged in that time, the column $mnop$ was equal by hypothesis. Let A be the area of the base MN, and B the area of the base mn; let x be the height of a column equal to MN gh, and having A for its base, and let y be the height of the column $mnop$. Then, since the column $mnop$ is equal to the lamina MN gh, we shall have $Ax = By$, and (Geometry, Sect. IV. Theor. IX.) $x : y = A : B$; but as the surface MN descends to gh in the same time that mn descends to op, x will represent the mean velocity of the lamina MN gh, and y the mean velocity of the column $mnop$. The preceding analogy, therefore, informs us, that the mean velocity of any lamina is to the velocity of the fluid issuing from the orifice reciprocally as the area of the orifice is to the area of the base of the lamina MN gh. Hence it follows, that, if the area of the orifice is infinitely small, with regard to the area of the base of the lamina into which the fluid is supposed to be divided, the mean velocity of the fluid at the orifice will be infinitely greater than that of the laminæ; that is, while the velocity at the orifice is finite, that of the laminæ will be infinitely small.

Fig. 58.

179. Before applying these principles to the theory of hydraulics, it may be proper to observe, that several distinguished philosophers have founded the science upon the same general law from which we have deduced the principles of hydrostatics (48). In this way they have represented the motion of fluids in general formulæ; but these formulæ are so complicated from the very nature of the theory, and the calculations are so intricate, and sometimes impracticable from their length, that they can afford no assistance to the practical engineer.

Definition.

Fig. 58.

180. If the water issues at mn with the same velocity V that a heavy body would acquire by falling freely through a given height H, this velocity is said to be due to the height H, and inversely the height H is said to be due to the velocity V.

Prop. I.

181. The velocity of a fluid issuing from an infinitely small orifice in the bottom or side of a vessel, is equal to that which is due to the height of the surface of the fluid above that orifice, the vessel being supposed constantly full.

Let AB, fig. 59, be the vessel containing the fluid, its velocity when issuing from the aperture mn will be that which is due to the height Dm, or equal to that which a heavy body would acquire by falling through that height. Because the orifice mn is infinitely small, the velocity of the laminæ into which the fluid may be supposed to be divided, will also be infinitely small. But since all the fluid particles, by virtue of their gravity, have a tendency to descend with the same velocity; and since the different laminæ of the fluid lose this velocity, the column $mnst$ must be pressed by the superincumbent column D mn; and calling S the specific gravity of the fluid, the moving force which pushes out the column $mnst$ will be $S \times Dm \times mn$ (art. 58). Now, let us suppose, that, when this moving force is pushing out the column $mnst$, the absolute weight of the column $mnop$, which may be represented by $S \times mn \times np$, causes itself to fall through the height np. Then, if V, U be the velocities impressed upon the columns $mnst$, and $mnop$, by the moving forces $S \times Dm \times mn$, and $S \times mn \times np$; these moving forces must be proportional to their effects, or to the quantities of motion which they produce, that is, to $V \times mnst$ and $U \times mnop$, because the quantity of motion is equal to the velocity and mass conjointly; hence we shall have $S \times Dm \times mn : S \times mn \times np = V \times mnst : U \times mnop$. But since the volumes $mnst$, $mnop$ are to one another as their heights mo, os, and as these heights are run through in equal times, and consequently represent the velocity of their motion, $mnst$ may be represented by $V \times mn$ and $mnop$ by $U \times mn$; therefore we shall have $S \times Dm \times mn : S \times mn \times np = V \times V \times mn : U \times U \times mn$, and dividing by mn, $S \times Dm : np = V^2 : U^2$. Now let v be the velocity due to the height Dm, then (see Mechanics) $np : U^2 = Dm : v^2$; but since $S \times Dm : S \times np = V^2 ; U^2$; then by (Euclid V. 15), and by permutation $Dm : V^2 = np : U^2$, therefore by substitution (Euclid V. 11), $Dm : V^2 = Dm : v^2$, and (Euclid V. 9), $V^2 = v^2$ or $V = v$. But V is the velocity with which the fluid issues from the orifice mn, and v the velocity due to the height Dm; therefore, since the velocities are equal, the proposition is demonstrated.

Fig. 59.

182. Cor. 1. If the vessel AB empties itself by the small orifice mn, so that the surface of the fluid takes successively the positions OP, QR, ST, the velocities with which the water will issue when the surfaces have these positions will be those due to the heights En, Fn, Gn, for in these different positions the moving forces are the columns Emn, Fmn, Gmn.

183. Cor. 2. Since the velocities of the issuing fluid when its surface is at E, F, G, are those due to the heights En, Fn, Gn, it follows from the properties of falling bodies (see Mechanics), that if these velocities were continued uniformly, the fluid would run through spaces equal to 2En, 2Fn, 2Gn respectively, in the same time that a heavy body would fall through En, Fn, Gn, respectively.

184. Cor. 3. As fluids press equally in all directions,

the preceding proposition will hold true, when the orifices are at the sides of vessels, and when they are formed to throw the fluid upwards, either in a vertical or an inclined direction, provided that the orifices are in these several cases at an equal distance from the upper surface of the fluid. This corollary holds also in the case mentioned in Cor. 1.

185. Cor. 4. When the fluid issues vertically, it will rise to a height equal to the perpendicular distance of the orifice from the surface of the fluid; for (see Mechanics), this is true of falling bodies in general, and must therefore be true in the case of water: owing to the resistance of the air, however, and the friction of the issuing fluid upon the sides of the orifice, jets of water do not exactly rise to this height.

186. Cor. 5. As the velocities of falling bodies are as the square roots of the heights through which they fall (see Mechanics), the velocity V of the effluent water when the surface is at E, will be to its velocity v when the surface is at G, as $\sqrt{\mathrm{E}n} : \sqrt{\mathrm{G}n}$, (Cor. 1.) that is, the velocities of fluids issuing from a very small orifice are as the square roots of the altitude of the water above these orifices. As the quantities of fluids discharged are as the velocities, they will also be as the square roots of the altitude of the fluid. This corollary holds true of fluids of different specific gravities, notwithstanding Belidor (*Architect. Hydraul.* tom. i. p. 187), has maintained the contrary; for though a column of mercury Dmn presses with 14 times the force of a similar column of water, yet the column $mnop$ (fig. 59) of mercury which is pushed out is also 14 times as heavy as a similar column of water; and as the resistance bears the same proportion to the moving force, the velocities must be equal.

187. Cor. 6. When a vessel is emptying itself, if the area of the laminæ into which we may suppose it divided, be everywhere the same, the velocity with which the surface of the fluid descends, and also the velocity of efflux, will be uniformly retarded. For as the velocity V with which the surface descends is to the velocity v at the orifice, as the area a of the orifice to the area A of the surface, then $\mathrm{V} : v = a : \mathrm{A}$; but the ratio of $a : \mathrm{A}$ is constant, therefore V varies as v, that is, $\mathrm{V} : \mathrm{V}' = v : v'$; but, (Cor. 1) $v : v' = \sqrt{h} : \sqrt{h'}$, h being the height of the surface above the orifice, therefore $\mathrm{V} : \mathrm{V}' = \sqrt{h} : \sqrt{h'}$. But this is the property of a body projected vertically from the earth's surface, and as the retarding force is uniform in the one case (see Mechanics), it must also be uniform in the other.

188. Cor. 7. If a cylindrical vessel be kept constantly full, twice the quantity contained in the vessel will run out during the time in which the vessel would have emptied itself. For (Cor. 2 and 6) the space through which the surface of the fluid at D would descend if its velocity continued uniform being 2 Dm, double of Dm the space which it actually describes in the time it empties itself, the quantity discharged in the former case will also be double the quantity discharged in the latter: because the quantity discharged when the vessel is kept full, may be measured by what the descent of the surface would be, if it could descend with its first velocity.

Scholium.

189. The reader will probably be surprised when he finds in some of our elementary works on hydrostatics, that the velocity of the water at the orifice is only equal to that which a heavy body would acquire by falling through *half* the height of the fluid above the orifice. This was first maintained by Sir Isaac Newton, who found that the diameter of the *vena contracta* was to that of the orifice as 21 to 25. The area therefore of the one was to the area of the other as 21^2 to 25^2, which is nearly the ratio of 1 to $\sqrt{2}$. But by measuring the quantity of water discharged in a given time, and also the area of the *vena contracta*, Sir Isaac found that the velocity at the *vena contracta* was that which was due to the *whole* altitude of the fluid above the orifice. He therefore concluded, that since the velocity at the orifice was to that at the *vena contracta*[1] as $1 : \sqrt{2}$, and in the latter velocity was that which was due to the whole altitude of the fluid, the former velocity, or that at the orifice, must be that which is due to only *half* that altitude, the velocities being as the square roots of the heights. Now the difference between this theory and that contained in the preceding proposition may be thus explained. The velocity found by the preceding proposition is evidently the vertical velocity of the filaments at E (fig. 59), which being immediately above the centre of the aperture mn are not diverted from their course, and have therefore their vertical equal to their absolute velocity. But the vertical velocity of the particles between C and E, and E and D, is much less than their absolute velocity, on account of the obliquity of their motion, and also on account of their friction on the sides of the orifice. The mean vertical velocity, consequently, of the issuing fluid will be much less than the vertical velocity of the particles at E, that is, than the velocity found by the above proposition, or that due to the height Dm. Now the velocity found by Sir Isaac Newton from measuring the quantity of water discharged, was evidently the mean velocity, which ought to be less than the velocity given by the preceding proposition, the two velocities being as $1 : \sqrt{2}$, or as $1 : 1.414$. The theorem of Newton therefore may be considered as giving the mean velocity at the orifice, while the proposition gives the velocity of the particles at D, or the velocity at the *vena contracta*.

Prop. II.

190. To find the quantity of water discharged from a very small orifice in the side or bottom of a reservoir, the time of discharge, and the altitude of the fluid, the vessel being kept constantly full, and any two of these quantities being given.

Let A be the area of the orifice mn; W the quantity of water discharged in the time T; H the constant height Dm of the water in the vessel, and let 16.087 feet be the height through which a heavy body descends in a second of time. Now, as the times of description are proportional to the square roots of the heights described, the time in which a heavy body will fall through the height H, will be found from the following analogy; $\sqrt{16.087} : \sqrt{\mathrm{H}} = 1 : \frac{\sqrt{\mathrm{H}}}{16.087}$, the time required. But as the velocity at the orifice is uniform, a column of fluid whose base is mn and altitude 2H (Prop. I. Cor. 2.) will issue in the time 16.087 $\sqrt{\mathrm{H}}$, or since A is the area of the orifice mn, $\mathrm{A} \times 2\mathrm{H}$ or

[1] When a fluid runs through a conical tube kept constantly full, the velocities of the fluid in different sections will be inversely as the area of the sections. For as the same quantity of fluid runs through every section in the same time, it is evident that the velocity must be greater in a smaller section, and as much greater as the section is smaller, otherwise the same quantity of water would not pass through each section in the same time. Now the area of the *vena contracta* is to the area of the orifice, as $1 : \sqrt{2}$, therefore the velocity at the *vena contracta* must be to the velocity at the orifice as $\sqrt{2} : 1$.

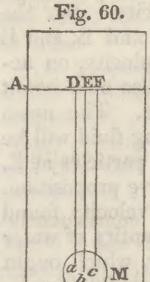
2HA will represent the column of fluid discharged in that time. Now since the quantities of fluid discharged in different times must be as the times of discharge, the velocity at the orifice being always the same, we shall have $\frac{\sqrt{H}}{16.087}:T = 2HA : W$, and (GEOMETRY, Sect. IV. Theor. VIII.) $\frac{W\sqrt{H}}{16.087} = 2HAT$ or $W = \frac{2HAT \times 16.087}{\sqrt{H}}$, and since $\frac{H}{\sqrt{H}} = \sqrt{H}$ we shall have $W = 2AT\sqrt{H} \times 16.087$, an equation from which we deduce the following formulæ, which determine the quantity of water discharged, the time of discharge, the altitude of the fluid, and the area of the orifice, any three of these four quantities being given:

$$W = 2AT\sqrt{H \times 16.087} \qquad A = \frac{W}{2T\sqrt{H \times 16.087}}$$

$$H = \frac{W^2}{4A^2T^2 \times 16.087} \qquad T = \frac{W}{2A\sqrt{H = 16.087}}$$

191. It is supposed in the preceding proposition that the orifice in the side of the vessel is so small, that every part of it is equally distant from the surface of the fluid. But when the orifice is large like M (fig. 60.), the depths of different parts of the orifice below the surface of the fluid are very different, and consequently the preceding formulæ will not give very accurate results. If we suppose the orifice M divided into a number of smaller orifices a, b, c, it is evident that the water will issue at a, with a velocity due to the height Da, the water at b, with a velocity due to the height Eb, and the water at c, with a velocity due to the height Fc. When the whole orifice, therefore, is opened, the fluid will issue with different velocities at different parts of its section. Consequently, in order to find new formulæ expressing the quantity of water discharged, we must conceive the orifice to be divided into an infinite number of areas or portions by horizontal planes; and by considering each area as an orifice, and finding the quantity which it will discharge in a given time, the sum of all these quantities will be the quantity discharged by the whole orifice M.

Fig. 60.



Prop. III.

192. To find the quantity of water discharged by a rectangular orifice in the side of a vessel kept constantly full.

Let ABD (fig. 61.) be the vessel with the rectangular orifice GL, and let AB be the surface of the fluid. Draw the lines MNOP, $mnop$, infinitely near each other, and from any point D draw the perpendicular DC meeting the surface of the fluid in C. Then regarding the infinitely small rectangle MO mo as an orifice whose depth below the surface of the fluid is H, we shall have by the first of the preceding formulæ, the quantity of water discharged in the time T, or $W = T\sqrt{16.087} \times \sqrt{CN} \times \overline{2MO \times Nn}$, CN being equal to H and $MO \times Nn$ to the area A. As the preceding formula represents the quantity of fluid discharged by each elementary rectangular orifice, into which the whole orifice GL is supposed to be divided, we must find the sum of all the quantities discharged in the time T, in order to have the total quantity afforded by the finite orifice in the same time. Upon DC as the principal axis, describe the parabola CHE, having its parameter P equal to 4DC. Continue FG and DK to H and E. The area NPpn may be expressed by $NP \times Nn$. But (CONIC SECTIONS, Part I. Prop. X.) $\overline{NP}^2 = CN \times P$ (P being the parameter of the parabola), therefore $NP = \sqrt{CN \times P}$, and multiplying by Nn we have $NP \times Nn = Nn\sqrt{CN \times P}$, which expresses the area NPpn. Now this expression of the elementary area being multiplied by the constant quantity $T\sqrt{16.087} \times \frac{MO}{\sqrt{\frac{1}{4}P}}$ gives for a product $T\sqrt{16.087} \times \sqrt{CN} \times \overline{2MO \times Nn}$, for $\sqrt{\frac{1}{4}P} = \frac{1}{2}\sqrt{P}$ and $\frac{MO \times \sqrt{P}}{\frac{1}{2}\sqrt{P}} = 2MO$. But this product is the very same formula which expresses the quantity of water discharged in the time T by the orifice MO om. Therefore, since the elementary area MPpm multiplied by the constant quantity $T\sqrt{16.087} \times \frac{MO}{\sqrt{\frac{1}{4}P}}$ gives the quantity of water discharged by the orifice MO om in a given time, and since the same may be proved of every other orifice of the same kind into which the whole orifice is supposed to be divided, we may conclude that the quantity of water discharged by the whole orifice GL will be found by multiplying the parabolic area FHED by the same constant quantity $T\sqrt{16.087} \times \frac{MO}{\sqrt{\frac{1}{4}P}}$. Now the area FHED is equal to the difference between the areas CDE and CFH. But (CONIC SECTIONS, Part I. Prop. X.) the area $CDE = \frac{2}{3}CD \times DE$; and since $P = 4CD$, and (CONIC SECTIONS, Part I. Prop. X.) $\overline{DE}^2 = CD \times P$ we have $\overline{DE}^2 = CD \times 4CD = 4CD^2$, that is $DE = 2CD$, then by substituting this value of DE in the expression of the area CDE, we have $CDE = \frac{4}{3}CD^2$. The area $CFH = \frac{2}{3}CF \times FH$, consequently the area $FHED = \frac{4}{3}CD^2 - \frac{2}{3}CF \times FH$, which, multiplied by the constant quantity, gives for the quantity of water discharged, ($\frac{1}{3}P^2$ being substituted instead of its equal $\frac{4}{3}CD^2$),

$$W = \frac{T\sqrt{16.087} \times MO \times \overline{\frac{1}{3}P^2 - \frac{2}{3}CF \times FH}}{\sqrt{\frac{1}{4}P}}.$$

But by the property of the parabola $FH^2 = CF \times P$ and $FH = \sqrt{CF \times P}$, therefore substituting this value of FH in the preceding formula, and also $\frac{1}{2}\sqrt{P}$ for its equal $\sqrt{\frac{1}{4}P}$ we have

$$W = \frac{T\sqrt{16.087} \times MO \times \overline{\frac{1}{3}P^2 - \frac{2}{3}CF \times \sqrt{CF \times P}}}{\frac{1}{2}\sqrt{P}}$$

and dividing by $\frac{1}{2}\sqrt{P}$ gives us

$$W = T\sqrt{16.087} \times MO \times \overline{\frac{2}{3}P\sqrt{P} - \frac{4}{3}CF \times \sqrt{CF}};$$

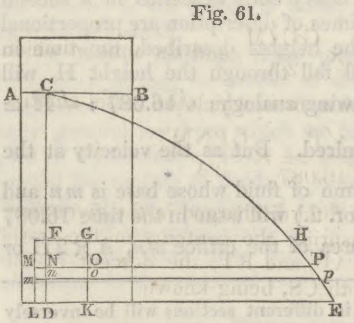
hence

$$T = \frac{W}{\sqrt{16.087} \times MO \times \frac{2}{3}P\sqrt{P} - \frac{4}{3}CF \times \sqrt{CF}},$$

$$MO = \frac{W}{T\sqrt{16.087} \times \frac{2}{3}P\sqrt{P} - \frac{4}{3}CF \times \sqrt{CF}},$$

$$P = \left[\frac{9W}{4T\sqrt{16.087}} + 3CF\sqrt{CF}\right]^{\frac{2}{3}},$$

Fig. 61.



and since P = 4CD

$$CD = \overline{\frac{9W}{16T\sqrt{16.087}} + 12CF \times \sqrt{CF}}\Big|^{\frac{2}{3}},$$

$$CF = \overline{\frac{9W}{16T\sqrt{16.087}} + \tfrac{1}{8}P\sqrt{P}}\Big|^{\frac{2}{3}}.$$

In these formulæ W represents the quantity of water discharged, T the time of discharge, MO the horizontal width of the rectangular orifice, P the parameter of the parabola = 4CD, CD the depth of the water in the vessel or the altitude of the water above the bottom of the orifice, and CF the altitude of the water above the top of the orifice. The vertical breadth of the orifice is equal to CD — CF.

193. Let x be the mean height of the fluid above the orifice, or the height due to a velocity, which, if communicated to all the particles of the issuing fluid, would make the same quantity of water issue in the time T, as if all the particles moved with the different velocities due to their different depths below the surface, then by Prop. II. the quantity discharged or $W = 2T \times MO \times \overline{CD - CF} \times \sqrt{x \times 16.087}$, the area of the orifice being $MO \times \overline{CD - CF}$, and by making this value of W equal to its value in the preceding article, we have the following equation:

$2T \times MO \times \overline{CD - CF} \times \sqrt{x \times 16.087} = T\sqrt{16.087} \times MO \times \overline{\tfrac{2}{3}P\sqrt{P} - \tfrac{4}{3}CF\sqrt{CF}}$, which, by division and reduction, and the substitution of $\tfrac{1}{4}P$ instead of CD its equal, becomes

$$x = \frac{\tfrac{4}{9}(P\sqrt{P} - \tfrac{4}{3}CF\sqrt{CF})^2}{4(\tfrac{1}{4}P - CF)^2}.$$

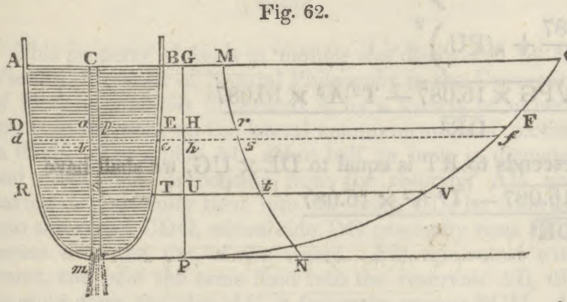
Now this value of x is evidently different from the distance of the centre of gravity of the orifice from the surface of the fluid, for this distance is $\frac{CD + CF}{2}$ or $\frac{\tfrac{1}{4}P + CF}{2}$. But in proportion as CE increases, the other quantities remaining the same, the value of x will approach nearer the distance of the centre of gravity of the orifice from the surface of the fluid; for when CF becomes infinite, the parabolic arch CHE will become a straight line, and consequently the mean ordinate of the curve, which is represented by the mean velocity of the water, will pass through the middle of FD or the centre of gravity of the orifice.

Prop. IV.

194. To find the time in which a quantity of fluid equal to ABRT, will issue out of a small orifice in the side or bottom of the vessel AB, that is, the time in which the surface AB will descend to RT.

Draw DE, de at an infinitely small distance, and parallel to AB. The lamina of fluid DdeE may be represent-

Fig. 62.



ed by $DE \times ob$; DE expressing the area of the surface. When the surface of the water has descended to DE, the quantity of fluid which will be discharged by an uniform velocity in the time T, will be $T\sqrt{16.087} \times 2A \times \sqrt{om}$, A being the area of the orifice, as in Prop. II. But as the variation in the velocity of the water will be infinitely small, when the surface descends from DE to de, its velocity may be regarded as uniform. The time, therefore, in which the surface describes the small height ob will be found by the following analogy; $T\sqrt{16.087} \times 2A \times \sqrt{om}$: $T = DE \times ob : \frac{DE \times ob}{\sqrt{16.087} \times 2A \times \sqrt{om}}$. Now as this formula expresses the time in which the surface descends from DE to de, and as the same may be shewn of every other elementary portion of the height CS, the sum of all these elementary times will give us the value of T, the time in which the surface AB falls down to RT. For this purpose draw GP equal and parallel to Cn, and upon it as an axis, describe the parabola PVQ, having its parameter P equal to 4GP. Continue the lines AB, DE, de, RT, so as to form the ordinates HF, hf, UV, of the parabola. Upon GP as an axis, describe a second curve, so that the ordinate GM may be equal to the area of the surface at AB, divided by the corresponding ordinate GQ of the parabola, and that the ordinate Hr may be the quotient of the area of the surface at DE divided by the ordinate HF. Now (Conic Sections, Part I. Prop. X.) $\overline{HF}^2 = HP \times P$, or $HF = \sqrt{HP} \times \sqrt{P}$, that is $\sqrt{HP} = \frac{HF}{\sqrt{P}}$, and since $om = HP$; $\frac{DE}{\sqrt{om}} = \frac{DE \times \sqrt{P}}{HF}$. But by the construction of the curve MN, we have $\frac{DE}{HF} = Hr$, consequently $\frac{DE}{\sqrt{om}} = Hr \times \sqrt{P}$. The elementary time, therefore, expressed by $\frac{DE \times ob}{\sqrt{16.087} \times 2A \times \sqrt{om}}$ will, by the different substitutions now mentioned, be $\frac{\overline{Hr \times ob}\sqrt{P}}{2A\sqrt{16.087}}$ or $\frac{\sqrt{P}}{2A\sqrt{16.087}} \times Hr \times ob$. But the factor $\frac{\sqrt{P}}{2A\sqrt{16.087}}$ consisting of constant quantities is itself constant, and the other factor $Hr \times ob$ represents the variable curvilineal area Hrsh. Now as the same may be shewn of every other element of the time T, compared with the corresponding elements of the area GUtM, it follows that the time T required, will be found by multiplying the constant quantity $\frac{\sqrt{P}}{2A\sqrt{16.087}}$ by the curvilineal area GUtM; therefore $T = \frac{\sqrt{P}}{\sqrt{16.087}} \times \frac{GUtM}{2A}$, and the time in which the surface descends to mn, or in which the vessel empties itself, will be equal to $\frac{\sqrt{P}}{\sqrt{16.087}} \times \frac{GPNM}{2A}$.

Cor. The quantity of fluid discharged in the given time T may be found by measuring the contents of the vessel AB between the planes AB, and RT, the descent of the surface AB, viz. the depth CS, being known.

Prop. V.

195. To find the time in which a quantity of fluid equal to

Motion of Fluids, &c.

ABRT will issue out of a small orifice in the side or bottom of the *cylindrical* vessel AB, that is, the time in which the surface AB will descend to RT.

Let us suppose that a body ascends through the height mC (fig. 63.) with a velocity increasing in the same manner as if the vessel AB were inverted, and the body fell from m to C. The velocity of the ascending body at different points of its path being proportional to the square roots of the heights described, will be expressed by the ordinates of the parabola PVQ. The line DE being infinitely near to de, as soon as the body arrives at b it will describe the small space bo or hH in a portion of time infinitely small, with a velocity represented by the ordinate HF. Now the time in which the body will ascend through the space mC or its equal PG will be $\frac{\sqrt{PG}}{\sqrt{16.087}}$, because $\sqrt{16.087} : \sqrt{PG} = \frac{\sqrt{PG}}{\sqrt{16.087}}$ (see MECHANICS); and if the velocity impressed upon the body when at C were continued uniformly, it would run through a space equal to 2GP or GQ in the time $\frac{\sqrt{PG}}{\sqrt{16.087}}$. But (DYNAMICS, 22.) the times of description are as the spaces described directly, and the velocities inversely, and therefore the time of describing the space 2GP or GQ uniformly, viz. the time $\frac{\sqrt{PG}}{\sqrt{16.087}}$ will be to the time of describing the space hH uniformly as $\frac{GQ}{GQ} : \frac{Hh}{HF}$, that is, as $\frac{GQ}{GQ}$ or $1 : \frac{\sqrt{PG}}{\sqrt{16.087}} = \frac{Hh}{HF} : \frac{\sqrt{PG}}{\sqrt{16.087}} \times \frac{Hh}{HF}$ the time in which the ascending body will describe Hh uniformly; but PG being equal to $\frac{1}{4}$P, the parameter of the parabola, we shall have $\sqrt{PG} = \sqrt{\tfrac{1}{4}P} = \tfrac{1}{2}\sqrt{P}$. Substituting this value of $\sqrt{PG}$ in the last formula, we shall have for the expression of the time of describing Hh uniformly $\frac{\frac{1}{2}\sqrt{P}}{\sqrt{16.087}} \times \frac{Hh}{HF}$. But by Prop. IV. the time in which the surface DH descends into the position dh, that is, in which it describes Hh is represented by $\frac{\sqrt{P}}{2A\sqrt{16.087}} \times Hr \times ob$ or $\frac{\sqrt{P}}{\sqrt{16.087}} \times \frac{Hr \times Hh}{2A}$. Therefore the time in which the ascending body moves through hH, is to the time in which the descending surface moves through Hh as $\frac{\frac{1}{2}\sqrt{P}}{\sqrt{16.087}} \times \frac{Hh}{HF} : \frac{\sqrt{P}}{\sqrt{1.6087}} \times \frac{Hr \times Hh}{2A}$, which expressions, after being multiplied by 2, and after substituting in the latter $\frac{DE}{HF}$ instead of Hr, which is equal to it by construction, will become $\frac{\sqrt{P}}{\sqrt{16.087}} \times \frac{Hh}{HF} : \frac{\sqrt{P}}{\sqrt{16.087}} \times \frac{DE \times Hh}{A \times HF}$, DE representing, in this and in the following proposition, the area of the surface of the fluid at D. Now, if we multiply the first of these expressions by DE, and the second by A, we shall find the two products equal; consequently (Euclid VI. 16.), the first expression is to the second, or the time of the body's ascent through hH is to the time of the surface's descent through Hh, as the area A of the orifice is to the area DE of the base of the cylindrical vessel; and as the same may be demonstrated of every elementary time in which the ascending body and the descending surface describe equal spaces, it follows that the whole time in which the ascending body will describe the height mC or PG, is to the whole time in which the surface AB will descend to mn, or in which the vessel will empty itself, as the area A of the orifice is to the area of the surface DE, that is, $A : DE = \sqrt{\frac{PG}{16.087}} : \sqrt{\frac{PG}{16.087}} \times \frac{DE}{A}$, the time in which the vessel AB will empty itself. If RTmn be the vessel, it may be shewn in the same manner, that the time in which it will empty itself will be $\sqrt{\frac{PU}{16.087}} \times \frac{DE}{A}$, DE being equal to RT. But the difference between the times in which the vessel ABmn empties itself, and the time in which the vessel RTmn empties itself, will be equal to the time required in the proposition, during which the surface AB descends to RT. This time therefore will be

$$T = \sqrt{\frac{PG}{16.087}} \times \frac{DE}{A} \sqrt{\frac{PU}{16.087}} \times \frac{DE}{A} = \frac{DE\sqrt{PG} - DE\sqrt{PU}}{A\sqrt{16.087}}$$

$$T = \frac{DE \times \overline{\sqrt{PG} - \sqrt{PU}}}{A\sqrt{16.087}}. \text{ Hence}$$

$$PU = \left(\frac{T,\ A\sqrt{16.087}}{DE} - \sqrt{PG}\right)^2$$

$$PG = \left(\frac{T,\ A\sqrt{16.087}}{DE} + \sqrt{PU}\right)^2$$

$$PG - PU \text{ or } UG = \frac{2T,\ A \times DE\sqrt{PG \times 16.087} - T^2 A^2 \times 16.087}{\overline{DE}^2}$$

As the quantity of fluid discharged while the surface AB descends to RT is equal to DE $\times$ UG, we shall have

$$W = DE \times \frac{2T,\ A \times DE\sqrt{PG \times 16.087} - T^2 A^2 \times 16.087}{\overline{DE}^2}$$

$$A = \frac{\overline{DE} \times \sqrt{PG} \times \sqrt{PU}}{T\sqrt{16.087}}$$

$$DE = \frac{T,\ A\sqrt{16.087}}{\sqrt{PG} - \sqrt{PU}}.$$

Motion of Fluids, &c.

Prop. VI.

196. If two cylindrical vessels are filled with water, the time in which their surfaces will descend through similar heights will be in the compound ratio of their bases, and the difference between the square roots of the altitudes of each surface at the beginning and end of its motion, directly, and the area of the orifices inversely.

Figs. 63 and 64.

Let AB mn, A′B′ $m'n'$ be the two vessels; then by the

Fig. 63.

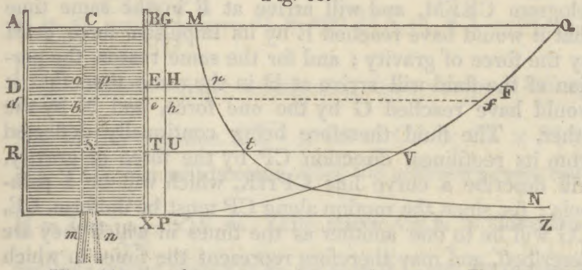


Fig. 64.

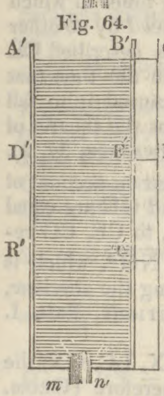


last proposition, the time T, in which the surface AB of the first descends to RT, will be to the time T′ in which the surface A′B′ of the second descends to R′T′ as $\frac{DE \times \sqrt{PG} \times \sqrt{PU}}{A\sqrt{16.087}}$ to $\frac{D'E' \times \sqrt{P'G'} - \sqrt{P'U'}}{A' \sqrt{16.087}}$, or by dividing by $\sqrt{16.087}$, as $\frac{DE \times \sqrt{PG} - \sqrt{PU}}{A}$ to $\frac{D'E' \times \sqrt{PG} - \sqrt{PU}}{A}$. Q.E.D.

197. Cor. Hence the time in which two cylindrical vessels full of water will empty themselves, will be in the compound ratio of their bases and the square roots of their altitudes directly, and the area of the orifices inversely; for in this time the surfaces AB, A′B′ descend to mn, $m'n'$ respectively, and therefore $\sqrt{PG} - PU = \sqrt{PG}$; since PU vanishes, the times will be as $\frac{DE \times \sqrt{PG}}{A}$ to $\frac{D'E' \times \sqrt{P'G'}}{A}$.

Prop. VII.

198. To explain the theory and construction of clepsydræ or water-clocks. Theory of clepsydræ or water-clocks.

A clepsydra, or water-clock, is a machine which, filled with water, measures time by the descent of the fluid surface. See Part III. on *Hydraulic Machinery*.

It has already been demonstrated in Prop. IV. that the times in which the surface AB descends to DE and RT, &c. are as the areas GM r H, GM t U, &c. If such a form therefore is given to the vessel that the areas GM r H, GM t U, &c. increase uniformly as the times, or are to one another as the numbers 1, 2, 3, 4, 5, &c. the times in which the surface AB descends to DE, and RT, &c. will be in the same ratio, and the vessel will form a machine for measuring time. If the vessel is cylindrical and empties itself in 12 hours, its altitude may be divided in such a manner that the fluid surface may take exactly an hour to descend through each division. Let the cylindrical vessel, for example, be divided into 144 equal parts, then the surface of the water, when the twelve hours begin to run, will be 144 parts above the bottom of the vessel; when one hour is completed, the surface will be 121 parts above the bottom and so on in the following manner:

Hours.	0	1	2	3	4	5	6	7	8	9	10	11	12
Distance of each Hour above the bottom.	144	121	100	81	64	49	36	25	16	9	4	1	0
Number of Parts in each Hour.	23	21	19	17	15	13	11	9	7	5	3	1	

For since the velocity with which the surface AB descends, the area of that surface being always the same, is as the square roots of its altitude above the orifice (Prop. I. Cor. 6); and since the velocities are as the times of description, the times will also be as the square roots of the altitudes, that is, when

12 11 10 9 &c. are the times,
144 121 100 81 will be the altitudes of the surface.

Prop. VIII.

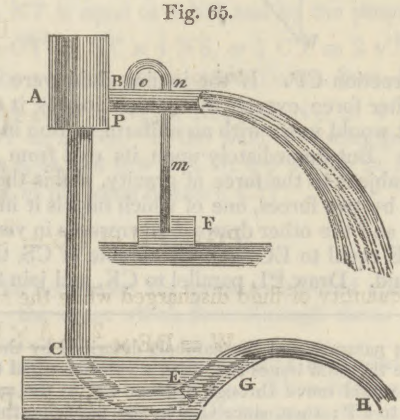
199. To explain the lateral communication of motion in fluids.

Lateral communication of motion in fluids.

This property of fluids in motion was discovered by M. Venturi, Professor of Natural Philosophy in the University of Modena, who has illustrated it by a variety of experiments in his work on the lateral communication of motion in fluids. Let a pipe AC, about half an inch in diameter and a foot long, proceeding from the reservoir AB, and having its extremity bent into the form CD, be inserted into the vessel CDG, whose side DG gradually rises till it passes over the rim of the vessel. Fill this vessel with water, and pour the same fluid into the reservoir AB, till, running down the pipe AC, it forms the stream EGH. In a short while, the water in the vessel CDG will be carried off by the current EG, which communicates its motion to the adjacent fluid. In the same way, when a stream of water runs through air, it drags the air along with it, and produces wind. Hence we have the water blowing machine, which conveys a blast to furnaces, and which will be described in a future part of this article. The lateral communication of motion, whether the surrounding fluid be air or water, is well illustrated by the following beauti-

Water blowing machine.

Fig. 65.



ful experiments of Venturi's. In the side of the reservoir AB (fig. 65), insert the horizontal pipe P about an inch and a half in diameter, and five inches long. At the point o of this pipe, about seven-tenths of an inch from the reservoir, fasten the bent glass tube $o\,n\,m$, whose cavity communicates with that of the pipe, whilst its other extremity is immersed in coloured water contained in the small vessel F. When water is poured into the reservoir AB, having no connection with the pipe C, so that it may issue from the horizontal pipe, the red liquor will rise towards m in the incurvated tube $o\,n\,m$. If the descending leg of this glass syphon be six inches and a half longer than the other, the red liquor will rise to the very top of the syphon, enter the pipe P, and running out with the other water, will in a short time leave the vessel F empty. Now, the cause of this phenomenon is evidently this: When the water begins to flow from the pipe P, it communicates with the air in the syphon $o\,n\,m$, and drags a portion along with it. The air in the syphon is therefore rarefied, and this process of rarefaction is constantly going on as long as the water runs through the horizontal pipe. The equilibrium between the external air pressing upon the fluid in the vessel F, and that included in the syphon, being thus destroyed, the red liquor will rise in the syphon, till it communicates with the issuing fluid, and is dragged along with it through the orifice of the pipe P, till the vessel F is emptied.

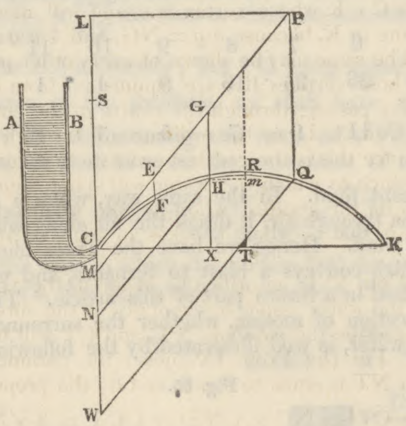
Prop. IX.

200. To find the horizontal distance to which fluids will spout from an orifice perforated in the side of a vessel, and the curve which it will describe.

Theory of vertical and oblique jets.

Let AB be a vessel filled with water, and C an orifice in its side, so inclined to the horizon as to discharge the fluid

Fig. 66.



in the direction CP. If the issuing fluid were influenced by no other force except that which impels it out of the orifice, it would move with an uniform motion in the direction CP. But immediately upon its exit from the orifice C, it is subject to the force of gravity, and is therefore influenced by two forces, one of which impels it in the direction CP, and the other draws it downwards in vertical lines. Make CE equal to EG, and CP double of CS, the altitude of the fluid. Draw PL parallel to CK, and join SL. Draw also EF, GH parallel to CN, and FM, HN parallel to CG, and let CM, CN represent the force of gravity, or the spaces through which it would cause a portion of fluid to descend in the time that this portion would move through CE, CG respectively, by virtue of the impulsive force. Now, it follows from the composition of forces (Dynamics, 135), that the fluid at C, being solicited in the direction CE by a force which would carry it through CE in the same time that the force of gravity would make it fall through CM, will describe the diagonal CF of the parallelogram CEFM, and will arrive at F in the same time that it would have reached E by its impulsive force, or M by the force of gravity; and for the same reason the portion of the fluid will arrive at H in the same time that it would have reached G by the one force, and N by the other. The fluid therefore being continually deflected from its rectilineal direction CP by the force of gravity, will describe a curve line CFHK, which will be a parabola; for since the motion along CP must be uniform, CE, CG will be to one another as the times in which they are described, and may therefore represent the times in which the fluid would arrive at E and G, if influenced by no other force. But in the time that the fluid has described CE gravity has made it fall through EF, and in the time that it would have described CG, gravity has caused it to fall through GH. Now, since the spaces are as the squares of the times in which they are described (Dynamics, 37, 2), we shall have $EF : GH = \overline{CE}^2 : \overline{CG}^2$. But on account of the parallelograms CEFM, CGHN, EF and GH are equal to CM and CN respectively, and MF, NH, to CE, CG respectively; therefore $CM : CN = \overline{MF}^2 : \overline{NH}^2$, which is the property of the parabola, CM, CN being the abscissæ, and MF, NH the ordinates (Conic Sections, Part. I. Prop. IX. Cor.).

201. On account of the parallels LP, CX, LC, GX, the triangles LCP, GCX are similar, and therefore (Geom. Sect. IV. Theor. XX.) $CG : CX = PC : PL$ and $GX : CX = CL : PL$. Hence $CG = \frac{CX \times PC}{PL}$, and $GX = \frac{CX \times CL}{PL}$, but since $PC = 2\,CS$, we have $CG = \frac{CX \times 2\,CS}{PL}$, and since $GX = GX - HX$, we shall have $GH = \frac{CX \times CL}{PL} - HX$. But as the parameter of the parabola CRK is equal to 4 CS (1), we have, by the property of this conic section, $\overline{NH}^2 = CN \times 4\,CS$, or $\overline{CG}^2 = 4\,\overline{GH} \times CS$; therefore, by substituting in this equation the preceding values of CG and GH, we shall have $\overline{CX}^2 \times CS = CX \times CL \times PL - HX \times \overline{PL}^2$. Now, it is evident, from this equation, that HX is nothing, or vanishes when $CX = 0$, or when $CX = \frac{CL \times PL}{CS}$, for HX being $= 0$, $HX \times \overline{PL}^2$, will also be $= 0$, and the equation will become $\overline{CX}^2 \times CS = CX \times CL \times PL$, or dividing by CX and CS, it becomes $CX = \frac{CL \times PL}{CS}$. But,

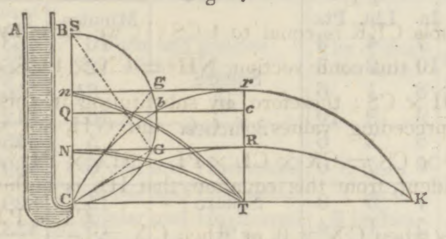
(1) The parameter of the parabola described by the issuing fluid, is equal to *four times* the altitude of the fluid above the orifice. For, since the fluid issues at C with a velocity equal to that acquired by falling through SC, if this velocity were continued uniform, the fluid would move through 2 CS or CP, in the same time that a heavy body would fall through SC. Draw PQ parallel to CS, and QW to CP; then, since Q is in the parabola, the fluid will describe CP uniformly in the same time that it falls through CW by the force of gravity, therefore $CW = CS$. Now $CP = 2\,CS$, and $\overline{CP}^2 = 4\,\overline{CS}^2 = 4 \times CS \times CS = 4 \times CS \times CW$; but it is a property of the parabola, that the square of the ordinate WQ or CP is equal to the product of the abscissa CW and the parameter, therefore 4 CS is the parameter of the parabola.

Motion of Fluids, &c.

when HX vanishes towards K, CX is equal to CK, consequently $CK = \frac{CL \times PL}{CS}$. Bisect CK in T, then $CT = \frac{CK}{2}$, and $CT = \frac{CL \times PL}{2\ CS}$. Draw TR perpendicular to CK, and TR will be found $= \frac{\overline{CL}^2}{4\ CS}$. Then, if H m be drawn at right angles to HX, we shall have $CX = CT - Hm = \frac{CL \times PL}{2\ CS} - Hm$ and $HX = RT - R = \frac{\overline{CL}^2}{4\ CS} - Rm$. After substituting these values of CX and HX in the equation $\overline{CX}^2 \times CS = CX \times CL \times PL - HX \times \overline{PL}^2$, it will become, after the necessary reductions, $\overline{Hm}^2 = \frac{PL^2}{CS} \times Rm$. The curve CRK is therefore a parabola whose vertex is R, its axis RT, and its parameter $\frac{\overline{PL}^2}{CS}$, R m being an abscissa of the axis, and H m its corresponding ordinate. Now, making a = CS, the altitude of the reservoir; R = radius; m = PL the sine of the angle PCL; and n = CL, the cosine of the same angle, CP being radius. Then CP : PL = R : m, therefore $PL \times R = CP \times m$, and dividing by R and substituting $2\,a$ or 2 CS, instead of its equal CP, we have $PL = \frac{2\,a\,m}{R}$, and by the very same reasoning, we have $CL = \frac{2\,a\,n}{R}$. Hence $RT = \frac{\overline{CL}^2}{4\ CS}$ will be $= \frac{4\,a^2\,n^2}{R^2}$ divided by $4\,a$, or $RT = a \times \frac{n^2}{R^2}$, and $CT = \frac{CL \times PL}{2\ CS} = \frac{4\,a^2\,m\,n}{2\,a \times R^2} = 2\,a \times \frac{m\,n}{R^2}$, and the parameter of the parabola $= \frac{PL^2}{CS} = \frac{4\,a^2\,m^2}{a \times R^2} = 4\,a \times \frac{m^2}{R^2}$.

202. Hence we have the following construction. With $\frac{1}{2}$ CS as radius, describe the semicircle SGC, which the

Fig. 67.



direction CR of the jet or issuing fluid meets in G. Draw GN perpendicularly to CS, and having prolonged it towards R, make GR equal to GN. From R let fall RT perpendicular to CK, and meeting it in T, and upon RT, CT, describe the parabola CRK having its vertex in R, this parabola will be the course of the issuing fluid. For, by the construction NR or CT = 2 GN, and on account of the similar triangles SGC, CGN, SC : SG = CG : GN; hence $SC \times GN = SG \times CG$, or 2 GN, or $CT = \frac{2\,SG \times CG}{SC}$. But from the similarity of triangles CS : CG = SG : GN and CS : CG = CG : CN, consequently, when CG is radius or = R, GN will be the sine m of the angle GCS, and CN its cosine n; and we shall then have, by Euclid VI. 16. and reduction $SG = \frac{CS \times m}{R}$, and $CG = \frac{CS \times n}{R}$. By substituting these values of SG and CG in the equation $CT = \frac{2\ SG \times CG}{SC}$, we have $CT = \frac{2}{SC} \times \frac{CS \times m}{R} \times \frac{CS \times n}{R} = \frac{2\ CS \times m \times CS \times n}{CS \times R \times R} = \frac{2\ CS \times m\,n}{R^2} = 2\,a \times \frac{m\,n}{R^2}$. But the parameter P of the parabola CRK is equal to $\frac{\overline{CT}^2}{RT}$, because it is a third proportional to the abscissa and its ordinate, therefore $P = \frac{4\,a^2 \times m^2\,n^2}{R^2 \times RT}$. Now RT = CN, and $CN = \frac{NG \times n}{m}$, because CN : NG = m : n, or $CN = RT = a \times \frac{n^2}{R^2}$ by substituting the preceding value of NG. Therefore, the parameter $P = \left(\frac{4\,a^2 \times m^2\,n^2}{R^4}\right) \div \left(\frac{a \times n^2}{R^2}\right) = 4\,a \times \frac{m^2}{R^2}$, which is the same value of the parameter as was found in the preceding article, and therefore verifies the construction.

203. Cor. 1. Since NG = GR and CT = TK, the amplitude or distance CT, to which the fluid will reach on a horizontal plane, will be 4 NG, or quadruple the sine of the angle formed by the direction of the jet and a vertical line, the chord of the arch CG, being radius.

204. Cor. 2. If S n be made equal to CN, and $n\,g$ be drawn parallel to CT, and $g\,r$ be made equal to $n\,g$; then, if the direction of the jet be C g, the fluid will describe the parabola C r K whose vertex is r, and will meet the horizontal line in K, because $n\,g$ = NG, and 4 $n\,g$ = 4 NG = CK. The same may be shewn of every other pair of parabolas, whose vertices R r are equidistant from $a\ c$, a horizontal line passing through the centre of the circle.

205. Cor. 3. Draw the ordinate $a\ b$ through the centre a, and since this is the greatest ordinate that can be drawn, the distance to which the water will spout, being equal to 4 a, will be the greatest when its line of direction passes through b, that is, when it makes an angle of 45° with the horizon.

206. Cor. 4. If an orifice be made in the vessel AB at N, and the water issues horizontally in the direction NG, it will describe the parabola NT, and CT will be equal to 2 NG. For (by Prop. IX. note) the parameter of the parabola NT is equal to 4 NS, and by the property of the parabola $\overline{CT}^2 = NC \times 4\ NS$, or $\frac{1}{2}\ CT = 2\sqrt{NC \times NS}$; but by the property of the circle (Geom. Sect. IV. Theor. XXVIII.) $\overline{NG}^2 = NC \times NS$, and $NG = \sqrt{NC \times NS}$, hence CT = 2 NG. If the fluid is discharged from the orifice at n, so that S n = CN, $n\,g$ will be = NG, and it will spout to the same distance CT.

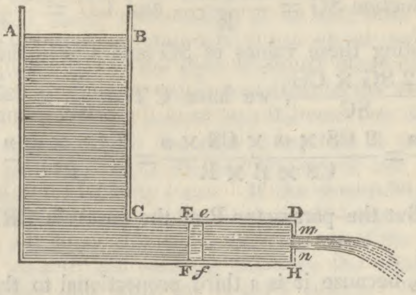
Prop. X.

207. To determine the pressure exerted upon pipes by the water which flows through them.

Fig. 68.

Let us suppose the column of fluid CD divided into an infinite number of laminæ EF $f\,e$. Then friction being abstracted, every particle of each lamina will move with the same velocity when the pipe CD is horizontal. Now, the velocity at the vena contracta $m\ n$ may be expressed by $\sqrt{A}$, A being the altitude of the fluid in the reservoir.

Fig. 68.



But the velocity at the *vena contracta* is to the velocity in the pipe, as the area of the latter is to the area of the former. Therefore δ being the diameter of the *vena contracta*, and d that of the pipe CD, the area of the one will be to the area of the other, as $\delta^2 : d^2$, (Geometry, Sect. VI. Prop. IV.) consequently we shall have $d^2 : \delta^2 = \sqrt{A} : \frac{\delta^2\sqrt{A}}{d^2}$, the velocity of the water in the pipe. But since the velocity $\sqrt{A}$ is due to the altitude A, the velocity $\frac{\delta^2\sqrt{A}}{d^2}$ will be due to the altitude $\frac{\delta^4 A}{d^4}$. Now, as each particle of fluid which successively reaches the extremity DH of the pipe, has a tendency to move with the velocity $\sqrt{A}$, while it moves only with the velocity $\frac{\delta^2\sqrt{A}}{d^2}$, the extremity D n of the pipe will sustain a pressure equal to the difference of the pressures produced by the velocities $\sqrt{A}$ and $\frac{\delta^2\sqrt{A}}{d^2}$, that is, by a pressure $A - \frac{\delta^4 A}{d^4}$, A representing the pressure which produces the velocity $\sqrt{A}$, and $\frac{\delta^4 A}{d^4}$ the pressure which produces the velocity $\frac{\delta^2\sqrt{A}}{d^2}$. But this pressure is distributed through every part of the pipe CD, consequently the pressure sustained by the sides of the pipe will be $A - \frac{\delta^4 A}{d^4}$.

208. Cor. 1. If a very small aperture be made in the side of the pipe, the water will issue with a velocity due to the height $A - \frac{\delta^4 A}{d^4}$. When the diameter δ of the orifice is equal to the diameter d of the pipe, the altitude becomes $A - A$ or nothing; and if the orifice is in this case below the pipe, the water will descend through it by drops. Hence we see the mistake of those who have maintained, that when a lateral orifice is pierced in the side of a pipe, the water will rise to a height due to the velocity of the included water.

209. Cor. 2. Since the quantities of water, discharged by the same orifice, are proportional to the square roots of the altitudes of the reservoir, or to the pressures exerted at the orifice, the quantity of water discharged by a lateral orifice may be easily found. Let W be the quantity of water discharged in a given time by the proposed aperture under the pressure A, and let w be the quantity discharged under the pressure $A - \frac{\delta^4 A}{d^4}$. Then $W : w = \sqrt{A} : \sqrt{A - \frac{\delta^4 A}{d^4}}$, consequently, $w \times \sqrt{A} = W \times \sqrt{A - \frac{\delta^4 A}{d^4}}$ and $w = \frac{W \times \sqrt{A - \frac{\delta^4 A}{d^4}}}{\sqrt{A}} = W\frac{\sqrt{d^4 - \delta^4}}{d^2}$. Therefore, since W may be determined by the experiments in the following chapter, w is known.

CHAPTER II.—ACCOUNT OF EXPERIMENTS ON THE MOTION OF WATER DISCHARGED FROM VESSELS, EITHER BY ORIFICES OR ADDITIONAL TUBES, OR RUNNING IN PIPES OR OPEN CANALS.

Ratio between the area of the vena contracta and the orifice.

210. In the preceding chapter, we have taken notice of the contraction produced upon the vein of fluid issuing from an orifice in a thin plate, and have endeavoured to ascertain its cause. According to *Sir Isaac Newton*, the diameter of the *vena contracta* is to that of the orifice as 21 to 25. *Poleni* makes it as 11 to 13; *Bernoulli* as 5 to 7; the *Chevalier de Buat* as 6 to 9; *Bossut* as 41 to 50; *Michelotti* as 4 to 5; *Venturi* as 4 to 5; *Bidone* as 33 to 50; and *Eytelwein* as 32 to 50. This ratio, however, is by no means constant. It varies with the form and position of the orifice, with the thickness of the plate in which the orifice is made, and likewise with the form of the vessel and the weight of the superincumbent fluid. But these variations are too trifling to be regarded in practice.—We shall now lay before the reader an account of the results of the experiments of different philosophers, but particularly those of the Abbé Bossut, to whom the science is deeply indebted both for the accuracy and extent of his labours.

Sect. I. *On the Quantity of Water discharged from Vessels constantly full by Orifices in thin Plates.*

211. The following table contains the results obtained by Michelotti when the orifices are vertical, and of a *square* or *circular* form, the altitude of the head of water varying from 6 feet to about 22 feet.

Michelotti's experiments.

Table I. *Shewing the Quantity of Water discharged by different Vertical Orifices.*

Altitude of Water above the centre of the orifice.				Size and form of the orifice.	Time of running.	Cubic feet of water discharged.

nts on
Motion
Fluids.

The coefficient obtained from these experiments is 0.625.

212. Messrs Brindley and Smeaton found that 20 cubic feet of water were discharged from orifices 1 inch square, in the following times, varying with the height of the water.

Height of water in feet.	Time of discharging 20 cubic feet.
1	562 seconds.
2	400
3	320
4	284
5	254

When the height of the water was 6 feet, and the orifice $\frac{1}{2}$ an inch square, 20 cubic feet were discharged in 17 minutes 33 seconds. The coefficient obtained from these experiments is 0.63.

213. When the water stands always at the upper surface of a rectangular aperture, without the upper edge, the aperture is called a *notch*. The following table shews the time of discharging 20 cubic feet, through notches 6 inches wide, of various depths.

Depth of the notch in inches.	Time of discharging 20 cubic feet.
1	436 seconds.
$1\frac{3}{8}$	295
$2\frac{5}{10}$	139
$3\frac{1}{8}$	93

214. In the following experiments by the Abbé Bossut which were frequently repeated in various ways, the orifice was pierced in a plate of copper about half a line thick. When the orifice is in the bottom of the vessel, it is called a *horizontal* orifice; and when it is in the side of it, it is called a *lateral* orifice.

TABLE II. *Shewing the Quantity of Water discharged in one minute, by orifices differing in form and position.*

Experiments on the Motion of Fluids.

215. From the results contained in the preceding table, we may draw the following conclusions.

1. That the quantities of water discharged in equal times by different apertures, the altitudes of the fluid being the same, are very nearly as the areas of the orifices. That is, if A or a represent the areas of the orifices, and W, w the quantities of water discharged,

$$W : w = A : a.$$

2. The quantities discharged in equal times by the same aperture, the altitude of the fluid being different, are to one another very nearly as the square roots of the altitudes of the water in the reservoir, reckoning from the centres of the orifices. That is, if H, h be the different altitudes of the fluid, we shall have $W : w = \sqrt{H} : \sqrt{h}$.

3. Hence we may conclude in general, that the quantities discharged in the same time by different apertures, and under different altitudes in the reservoir, are in the compound ratio of the areas of the orifices, and the square roots of the altitudes. Thus, if W, w be the quantities discharged in the same time from the orifices A, a, under the same altitude of water; and if W′, w be the quantities discharged in the same time by the same aperture a under different altitudes, H, h: then by the first of the two preceding articles

$W : w = A : a$, and by the second

$w : W = \sqrt{H} : \sqrt{h}$. Multiplying these analogies together, gives us

$$Ww : W'w = A\sqrt{H} : a\sqrt{h}, \text{ and by dividing by } w,$$
$$W : W' = A\sqrt{H} : a\sqrt{h}.$$

This rule is sufficiently correct in practice; but when great accuracy is required, the following remarks must be attended to.

4. Small orifices discharge less water in proportion than great ones, the altitude of the fluid being the same. The circumferences of the small orifices being greater in proportion to the issuing column of fluid than the circumferences of greater ones, the friction, which increases with the area of the rubbing surfaces, will also be greater, and will therefore diminish the velocity, and consequently the quantity discharged.

5. Hence of several orifices whose areas are equal, that which has the smallest circumference will discharge more water than the rest under the same altitude of fluid in the reservoir, because in this case the friction will be least. Circular orifices, therefore, are the most advantageous of all, for the circumference of a circle is the shortest of all lines that can be employed to inclose a given space.

6. In consequence of a small increase which the contraction of the vein of fluid undergoes, in proportion as the altitude of the water in the reservoir augments, the quantity discharged ought also to diminish a little as that altitude increases.

By attending to the preceding observations, the results of theory may be so corrected, that the quantities of water discharged in a given time may be determined with the greatest accuracy possible.

Comparison between the theoretical and real discharges from a circular orifice.

216. The Abbé Bossut has given the following table containing a comparison of the theoretical with the real discharges, for an orifice one inch in diameter, and for different altitudes of the fluid in the reservoir. The real discharges were not found immediately by experiment, but were determined by the precautions pointed out in the preceding articles, and may be regarded to be as accurate as if direct experiments had been employed. The fourth column was computed by M. Prony.[1]

15	16968	10472	1 to 0.61716
1	2	3	4

Deduction from the preceding table.

217. It is evident from the preceding table, that the theoretical, as well as the real discharges, are nearly proportional to the square roots of the altitudes of the fluid in the reservoir. Thus, if we take the altitudes 1 and 4, whose square roots are as 1 to 2, the real discharges taken from the table are 2722, 5436, which are to one another very nearly as 1 to 2, their real ratio being as 1 to 1.997.

The fourth column of the preceding table also shews us that the theoretical are to the real discharges nearly in the ratio of 1 to 0.62, or more accurately, as 1 to 0.61938; therefore 0.62 is the number by which we must multiply the discharges as found by the formulæ in the preceding chapter, in order to have the quantities of water actually discharged.

Application and use of the preceding table.

218. In order to find the quantities of fluid discharged by orifices of different sizes, and under different altitudes of water in the reservoir, we must use the table in the following manner. Let it be required, for example, to find the quantity of water furnished by an orifice three inches in diameter, the altitude of the water in the reservoir being 30 feet. As the real discharges are in the compound ratio of the area of the orifices, and the square roots of the altitudes of the fluid (art. 215, No. 3), and as the theoretical quantity of water discharged by an orifice one inch in diameter, is by the second column of the table 16918 cubic inches in a minute, we shall have this analogy, $1\sqrt{15}:9\sqrt{30}=16968:215961$ cubic inches, the quantity required. This quantity being diminished in the ratio of 1 to .62, being the ratio of the theoretical to the actual discharges, gives 133896 for the real quantity of water discharged by the given orifice. But (by No. 5 of art. 215), the quantity discharged ought to be a little greater than 133896, because greater orifices discharge more than small ones; and by No. 6 the quantity ought to be less than 133896, because the altitude of the fluid is double that in the table. These two causes therefore having a tendency to increase and diminish the quantity deduced from the preceding table, we may regard 133896 as very near the truth. Had the orifice been less than one inch, or the altitude less than 15 feet, it would have been necessary to diminish the preceding answer by a few cubic inches. Since the velocities of the issuing fluid are as the quantities discharged, the preceding results may be employed also to find the real velocities from those which are deduced from theory.

To determine the velocity.

219. As the velocity of falling bodies is 16.087 feet per second, the velocity due to 16.087 feet will be 32.174 feet per second, and as the velocities are as the square roots of the height, we shall have $\sqrt{16.087}:\sqrt{H}=32.174:V$ the velocity due to any other height, consequently $V=\frac{32.174\sqrt{H}}{\sqrt{16.087}}=\frac{32.174\sqrt{H}}{4.011}=8.016\sqrt{H}$, so that 8.016 is the coefficient by which we must always multiply the altitude of the fluid in order to have its theoretical velocity.

220. The following are the coefficients according to various authors, or the ratio of the theoretical to the real discharges from a circular orifice:

Michelotti	0.649
———	0.625
Borda	0.646
Venturi	0.640
Eytelwein	0.640
Hachette	0.690
Newton	0.707
Helsham	0.705
Brindley	0.631
Smeaton	0.631
Banks	0.750
Bossut	0.610
Rennie[1]	0.621

SECT. II. *On the Quantity of Water discharged from Vessels constantly full, by small Tubes adapted to Circular Orifices.*

Quantities of water discharged by small tubes.

221. The difference between the actual discharges, and those deduced from theory, arises from the contraction of the fluid vein, and from the friction of the water against the circumference of the orifice. If the operation of any of these causes could be prevented, the quantities of water actually discharged would approach nearer the theoretical discharges. There is no probability of diminishing friction in the present case by the application of unguents; but if a short cylindrical tube be inserted in the orifice of the vessel, the water will follow the sides of the tube, the contraction of the fluid vein will be in a great measure prevented, and the actual discharges will approximate much nearer to those deduced from theory, than when the fluid issues through a simple orifice.

When the cylindrical tube is two inches long and two in diameter, the fluid vein is contracted as in simple orifices.

222. If a cylindrical tube two inches long, and two inches in diameter, be inserted in the reservoir, and if this orifice is stopped by a piston till the reservoir is filled with water, the fluid, when permitted to escape, will not follow the sides of the tube, that is, the tube will not be filled with water, and the contraction in the vein of fluid will take place in the same manner as if the orifice were pierced in a thin plate. When the cylindrical tube was one inch in diameter, and two inches long, the water followed the sides of the tube, and the vein of fluid ceased to contract. While M. Bossut was repeating this experiment, he prevented the escape of the fluid by placing the instrument

[1] *Philosophical Transactions*, 1831.

[Ex]peri-[me]nts on [the] Motion of [F]luids. [Fig.] 69.

MN (see fig. 69.), consisting of a handle and a circular head, upon the interior extremity of the tube, and found, to his great surprise, that when he withdrew the instrument MN, to give passage to the water, it sometimes followed the sides of the tube, and sometimes detached itself from them, and produced a contraction in the fluid vein similar to that which took place when the first tube was employed. After a little practice, he could produce either of these effects at pleasure. The same phenomenon was exhibited when the length of the tube was diminished to one inch six lines; only it was more difficult to make the fluid follow the circumference of the tube. This effect was still more difficult to produce when its length was reduced to one inch; and when it was so small as half an inch, the water uniformly detached itself from its circumference, and formed the *vena contracta*.

223. Table IV. *Shewing the Quantities of Water discharged by Cylindrical Tubes one inch in diameter with different lengths.*

[Qu]antities [of f]luid dis[cha]rged [fro]m cylin[dric]al tubes [of t]he same [dia]meters [but] diffe[ren]t [len]gths.

	Variable lengths of the tubes expressed in lines.		Cubic inches discharged in a minute.
Constant altitude of the fluid above the superior base of the tube being 11 feet 8 inches and 10 lines.	The tube being filled with the issuing fluid.	48	12274
		24	12188
		18	12168
	The tube not filled with the issuing fluid.	18	9282

The experiments in the preceding table were made with tubes inserted in the bottom of the vessel. When the tubes were fixed horizontally in the side of the reservoir, they furnished the very same quantities of fluid, their dimensions and the altitude of the fluid remaining the same.

It appears from the preceding results, that the quantities of water discharged increase with the length of the tube, and that these quantities are very nearly as the square roots of the altitudes of the fluid above the interior orifice of the vertical tube.

We have already seen that the theoretical are to the real discharges, as 1 to 0.62, or nearly as 16.1 to 10. But by comparing the two last experiments in the preceding table, it appears that the quantity of fluid discharged by a cylindrical tube where the water follows its sides, is to the quantity discharged by the same tube when the *vena contracta* is formed, as 13 to 10; and since the same quantity must be discharged by the latter method as by a simple orifice, we may conclude that the quantity discharged according to theory, and that which is discharged by a cylindrical tube and by a simple orifice, are to one another very nearly as the numbers 16, 13, 10. Though the water therefore follows the sides of the cylindrical tube, the contraction of the fluid vein is not wholly destroyed; for the difference between the quantity discharged in this case, and that deduced from theory, is too great to be ascribed to the increase of friction which arises from the water following the circumference of the tube.

224. In order to determine the effect of tubes of different diameters, under different altitudes of water in the reservoir, M. Bossut instituted the experiments, the results of which are exhibited in the following table.

Experiments on the Motion of Fluids.

Table V. *Shewing the Quantities of Water discharged by Cylindrical Tubes two inches long, with different Diameters.*

Quantities of water discharged by cylindrical tubes of the same length but different diameters.

Constant altitude of the water above the orifice.		Diameter of the Tube.		Quantity of water discharged in a minute.
Feet.	Inches.		Lines.	Cubic inches.
3	10	The tube being filled with the issuing fluid.	6	1689
			10	4703
		The tube not filled with the issuing fluid.	6	1293
			10	3598
2	0	The tube being filled with the issuing fluid.	6	1222
			10	3402
		The tube not filled with the issuing fluid.	6	935
			10	2603

225. By comparing the different numbers in this table, we may conclude,

1. That the quantities of water discharged by different cylindrical tubes of the same length, the altitude of the fluid remaining the same, are nearly as the areas of the orifices, or the squares of their diameters.
2. That the quantities discharged by cylindrical tubes of the same diameter and length, are nearly as the square roots of the altitude of the fluid in the reservoir.
3. Hence the quantities discharged during the same time, by tubes of different diameters, under different altitudes of fluid in the reservoir, are nearly in the compound ratio of the squares of the diameters of the tube, and the square roots of the altitudes of the water in the reservoir.
4. By comparing these results with those which were deduced from the experiments with simple orifices, it will be seen that the discharges follow the same laws in cylindrical tubes as in simple orifices.

226. Table VI. *Comparison of the Theoretical with the Real Discharges from a Cylindrical Tube one inch in Diameter, and two inches long.*

Comparison of the theoretical with the real discharges in *cylindrical* tubes.

Experiments on the Motion of Fluids.

The above table is deduced from the foregoing experiments, and contains a comparative view of the quantities of water discharged by a simple orifice, according to theory, and those discharged by a cylindrical tube of the same diameter under different altitudes of water. The numbers might have been more accurate by attending to some of the preceding remarks; but they are sufficiently exact for any practical purpose. The fourth column, containing the ratio between the theoretical and actual discharges, was computed by M. Prony.

By comparing the preceding table with that in art. 216, we shall find that cylindrical tubes discharge a much greater quantity of water than simple orifices of the same diameter, and that the quantities discharged are as 81 to 62 nearly. This is a curious phenomenon, and will be afterwards explained.

227. The application of this table to other additional tubes under different altitudes of the fluid, not contained in the first column, is very simple. Let it be required, for example, to find the quantity of water discharged by a cylindrical tube, 4 inches in diameter, and 8 inches long, the altitude of the fluid in the reservoir being 25 feet. In order to resolve this question, find (by art. 218) the theoretical quantity discharged, which in the present instance will be 350490 cubic inches, and this number diminished in the ratio of 1 to 0.81 will give 284773 for the quantity required. The length of the tube in this example was made 8 inches, because, when the length of the tube is less than twice its diameter, the water does not easily follow its interior circumference. If the tube were longer than 8 inches, the quantity of fluid discharged would have been greater, because it uniformly increases with the length of the tube; the greatest length of the tube being always small, in comparison with the altitude of the fluid in the reservoir.

228. Hitherto we have supposed the tube to be exactly cylindrical. When its interior surface, however, is conical, the quantities discharged undergo a considerable variation, which may be estimated from the following experiments of the Marquis Poleni, published in his work, *De Castellis per quæ derivantur Fluviorum aquæ*, which appeared at Padua in 1718.

Experiments on the Motion of Fluids.

TABLE VII. *Shewing the Quantities of Water discharged by Conical Tubes of different Diameters.*

Quantities of water discharged by *conical* tubes, according to the experiments of M. Poleni.

		Apertures employed.	Interior diameter.	Exterior diameter.	Quantity discharged in a min. in cubic feet.	Time in which 73035 cub. in. were discharged.
Constant altitude of the water in the reservoir, 256 lines, or 1 foot 9 inches and 4 lines.	Length of each tube 92 lines, or 7 inches 8 lines.	Orifice in a thin plate,	26 lines	26 lines	15877	4′ 36″
		Cylindrical tube, .	26 ...	26 ...	23434	3′ 7″
		1st Conical tube, .	33 ...	26 ...	24758	2′ 57″
		2d Conical tube, .	42 ...	26 ...	24619	2′ 58″
		3d Conical tube, .	60 ...	26 ...	24345	3′ 0″
		4th Conical tube, .	118 ...	26 ...	23687	3′ 5″

From these experiments we are authorized to conclude, 1. That the real discharges are less than those deduced from theory, which in the present case is 27425 cubic inches in a minute; and, 2. That when the interior orifice of the tube is enlarged to a certain degree, the quantity discharged is increased; but that when this enlargement is too great, a contraction takes place without the exterior orifice, and the quantity discharged suffers a diminution. If the smallest base of the conical tube be inserted in the side of the reservoir, it will furnish more water than a cylindrical tube whose diameter is equal to the smallest diameter of the conical tube; for the divergency of its sides changes the oblique motion which the particles would otherwise have had, when passing from the reservoir into the tube.

229. The experiments of Poleni and Bossut having been made only with tubes of a conical and cylindrical form, M. Venturi was induced to institute a set of experiments, in which he employed tubes of the various forms exhibited in fig. 69. The results of his researches are contained in the following table, for which we have computed the column containing the number of cubic inches discharged in one minute, in order that the experiments of the Italian philosopher may be more easily compared with those which are exhibited in the preceding tables. The constant altitude of the water in the reservoir was 32.5 French inches, or 34.642 English inches. The quantity of water which flowed out of the vessel in the times contained in the first column was 4 French cubic feet, or 4.845 English cubic feet. The measures in the table are all English, unless the contrary be expressed.

Experiments of Venturi with tubes of various forms.

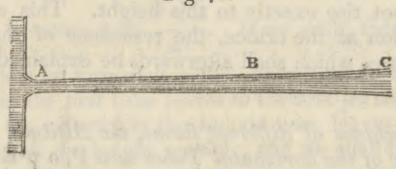
10	The tube F, consisting of a cylindrical tube 3.2 inches long, and 1.376 inches in diameter, interposed between the two conical parts of the preceding, ...	28.5	14516

230. These experiments of Venturi inform us of a curious fact, extremely useful to the practical hydraulist. They incontestably prove, that when water is conveyed through a straight cylindrical pipe of an unlimited length, the discharge of water may be increased only by altering the form of the terminations of the pipe; that is, by making the end of the pipe A, fig. 70, of the same form as the *vena*

Fig. 70.



contracta, and by forming the other extremity BC into a truncated cone, having its length BC about nine times the diameter of the cylindrical tube AB, and the aperture at C to that at B, as 18 to 10. By giving this form to the pipe, it will discharge more than twice as much water in a given time, the quantity discharged by the cylindrical pipe being to the quantity discharged by the pipe of the form ABC, as 10 to 24.

231. M. Venturi also found, that the quantities of water discharged out of a straight tube, a curved tube forming a quadrantal arc, and an elbowed tube with an angle of 90°, each branch having a horizontal position, are to one another nearly as the numbers 70, 50, 45. Hence we see the disadvantages of sinuosities and bendings in conduit pipes. In the construction of hydraulic machines, any variation in the internal diameter of the pipe ought to be carefully avoided, excepting those alterations at the extremities which we have recommended in the preceding paragraph.

232. It appears from the researches of Eytelwein, that when the shortest tube that will make the water follow its sides is applied to the reservoir, the quantity discharged will be to that deduced from theory, as 0.810 to 1.000, and the multiplier for finding the velocity will be 6.5. When the lengths of the tubes are increased from *two* to *four* times their diameter, the ratio of the actual and theoretical discharge will be 0.822 to 1.000, and the constant multiplier for finding the velocity will be 6.6. In employing a conical tube approaching to the figure of the *vena contracta*, the ratio of the discharges was as 0.92 to 1.00, and when its edges were rounded off, as 0.98 to 1.00 computing from its least section. He found also that the smallest quantity of water was discharged, when the interior extremity of the tube projected within the reservoir, the quantity furnished in this case being reduced to one half of what was discharged when the tube had its proper position.

Reason why cylindrical tubes furnish more water than orifices of the same diameter.

233. When a cylindrical tube is applied to an orifice, the oblique motion of the particles which enter it is diminished; the vertical velocity of the particles, therefore, is increased, and consequently the quantity of water discharged. M. Venturi maintains that the pressure of the atmosphere increases the expense of water through a simple cylindrical tube, and that in conical tubes, the pressure of the atmosphere increases the expenditure in the ratio of the exterior section of the tube to the section of the contracted vein, whatever be the position of the tube.

Best form for tubes employed to discharge water.

234. Of all the tubes that can be employed for discharging water, that is the most advantageous which has the form of a contracted vein. Hence, it will be a truncated cone with its greatest base next the reservoir, having its length equal to half the diameter of that base, and the area of the two orifices as 8 to 5, or their diameters in the subduplicate ratio of these numbers, viz. as $\sqrt{8} : \sqrt{5}$.

SECT. III.—*Experiments on the Exhaustion of Vessels.*

Difficulty in determining the time when a vessel is completely exhausted.

235. It is almost impossible to determine the exact time in which any vessel of water is completely exhausted. When the surface of the fluid has descended within a few inches of the orifice, a kind of conoidal funnel is formed immediately above the orifice. The pressure of the superincumbent column being therefore removed, the time of exhaustion is prolonged. The water falls in drops; and it is next to impossible to determine the moment when the vessel is empty. Instead, therefore, of endeavouring to ascertain the time in which vessels are completely exhausted, the Abbé Bossut has determined the times in which the superior surface of the fluid descends through a certain vertical height, and his results will be found in the following table:—

Experiments on the Motion of Fluids.

TABLE IX. *Shewing the Times in which Vessels are partly exhausted.*

Primitive altitude of the water in the vessel.	Constant area of a horizontal section of the vessel.	Diameter of the circular orifice.	Depression of the upper surface of the fluid.	Time in which this depression takes place.
Paris Feet.	Square Feet.	Inches.	Feet.	Min. Sec.
11.6666	9	1	4	7 $25\frac{1}{2}$
		2	4	1 52
		1	9	20 $24\frac{1}{2}$
		2	9	5 6
PG	DE	$\sqrt{\frac{A}{.7854}}$	PG—PU	T

Comparison of the experiments with the results of theory. Figs. 63 & 64.

236. In order to compare these experimental results with those deduced from theory, we must employ the formula (in Prop. V. 195) where the time in which the surface descends through any height is $\dfrac{T=DE\times\sqrt{PG}-\sqrt{PU}}{A\sqrt{16.087}}$, in which DE is the area of a section of the vessel, PG the primitive altitude of the surface above the centre of the orifice, PU the altitude of the surface after the time T is elapsed, A the area of the orifice, and 16.087 the space through which a heavy body descends in one second of time. That the preceding formula may be corrected, we must substitute 0.62 A, or $\frac{5A}{8}$, instead of A, in the formula, 0.62, A being the area of the *vena contracta;* and as the measures in the preceding table are in Paris feet, we must use 15.085, instead of 16.087, the former being the distance in Paris feet, and the latter the distance in English feet, which falling bodies describe in a second. The formula, therefore, will become $T=\dfrac{DE\times\sqrt{PG-PU}}{0.62\,A\sqrt{15.085}}$, and when the computations are made for the different diameters of the orifices, and the different depressions of the fluid surface, the results will be had, which are exhibited in the last column of the following table, containing the values of T, according to theory and experience.

Experiments on the Motion of Fluids.

TABLE X. *Comparison of the Results of Theory with those of Experiment.*

Diameter of the circular orifice.	Depression of the upper surface of the fluid.	Time of the depression of the surface by experiment.	Time of the depression of the surface by the formula.	Difference between the theory and the experiments.
Inches.	Feet.	Min. Sec.	Min. Sec.	Seconds.
1	4	7 $25\frac{1}{2}$	7 22.36	3.14
2	4	1 52	1 50.59	1.41
1	9	20 $24\frac{1}{2}$	20 16	8.50
2	9	5 6	5 4	2.00

It appears from this table that the times of discharge, by experiment, differ very little from those deduced from the corrected formula; and that the latter always err in defect. This may arise from 0.62 being too great a multiplier for finding the corrected diameter of the orifice. When the orifices are in the sides of the reservoir, the altitude PG, PU of the surface may be reckoned from the centre of gravity of the orifice, unless when it is very large.

SECT. IV. *Experiments on Vertical and Oblique Jets.*

Vertical jets do not rise to the same altitude as that of their reservoirs.

237. We have already seen that, according to theory, vertical jets should rise to the same altitude as that of the reservoirs from which they are supplied. It will appear, however, from the following experiments of Bossut, that jets do not rise exactly to this height. This arises from the friction at the orifice, the resistance of the air, and other causes which shall afterwards be explained.

Fig. 71.

TABLE XI. *Containing the Altitudes to which Jets rise through Adjutages of different forms, the Altitude of the Reservoir being Eleven Feet, reckoning from the upper surface of the horizontal Tubes* m n P, o p R.

Diameter of the horizontal tubes *m* P, *o* R, each being six feet long.	Form of the orifices.	References to Fig. 71.	Diameter of the orifice.	Altitude of the jet when rising vertically, reckoning from *m*.	Altitude of the jet when inclined a little to the vertical.	Description of the jets.

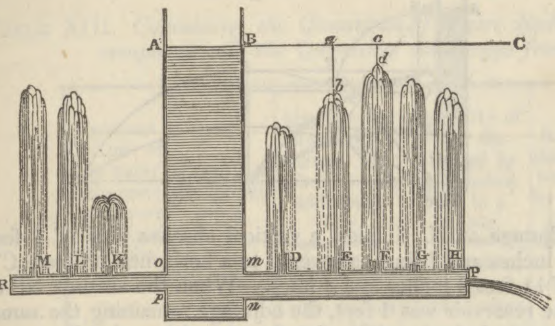
Experiments on the Motion of Fluids.

238. It appears, from the three first experiments of the preceding table, that *great jets rise higher than small ones;*

Fig. 71.



Ratio between the diameters of the tube and the adjutage for giving a maximum height to the jet.

and from the three last experiments, that *small jets rise higher than great ones when the horizontal tube is very narrow.* There is, therefore, a certain proportion between the diameter of the horizontal tube and that of the adjutage or orifice, which will give a maximum height to the jet. This proportion may be found in the following manner. Let D be the diameter of the tube, d that of the adjutage, a the altitude B m of the reservoir, b the velocity along the tube; and as the velocity at the adjutage is constant, it may be expressed by $\sqrt{a}$. Now (art. 189, note) the velocity in the tube is to the velocity at the adjutage as the area of their respective sections, that is, as the square of the diameter of the one is to the square of the diameter of the other. Therefore, $\sqrt{a} : b = D^2 : d^2$, and, consequently, $b = \frac{d^2 \sqrt{a}}{D^2}$. If there is another tube and another adjutage, the corresponding quantities may be the same letters in the Greek character, viz. Δ, δ, α, β, and we shall have the equation $\beta = \frac{\delta^2 \sqrt{\alpha}}{\Delta^2}$. If we wish, therefore, that the two jets be furnished in the same manner, then if the velocity in the first tube leaves to the first jet all the height possible, the velocity in the second tube leaves also to the second jet all the height possible, and we shall have $b = \beta$, or $\frac{d^2 \sqrt{a}}{D^2} = \frac{\delta^2 \sqrt{\alpha}}{\Delta^2}$. Hence $D^2 : \Delta^2 = d\, d \sqrt{a} : \delta\, \delta \sqrt{\alpha}$, that is, *the squares of the diameters of the horizontal tubes ought to be to one another in the compound ratio of the squares of the diameters of the adjutages, and the square roots of the altitudes of the reservoir.* Now, it appears from the experiments of Mariotte (*Traité du Mouvement des Eaux*), that when the altitude of the reservoir is 16 feet, and the diameter of the adjutage six lines, the diameter of the horizontal tube ought to be 28 lines and a half. By taking this as a standard, therefore, the diameters of the horizontal tube may be easily found by the preceding rule, whatever be the altitude of the reservoir and the diameter of the adjutage.

It results from the three last experiments, that the jets rise to the smaller height when the adjutage is a cylindrical tube (see D, fig. 71.), that a conical adjutage throws the fluid very much higher, and that when the adjutage is a simple orifice the jet rises highest of all.

Fig. 71.

239. By comparing the preceding experiments with those of Mariotte, it appears, that *the differences between the heights of vertical jets, and the heights of the reservoir, are nearly as the squares of the heights of the jets.* Thus, $a\,b : c\,d = \overline{E\,b^2} : \overline{F d^2}$; therefore, if $a\,b$ be known by experiment, we shall have $c\,d = \frac{a\,b \times F\,d^2}{E\,b^2}$, and by adding $c\,d$ to F d, we shall have the altitude of the reservoir. But if F c were given, and it were required to find F d, the height of the jet, we have, by the preceding analogy, $\overline{F\,d^2} = \frac{\overline{E\,b^2} \times c\,d}{a\,b}$. But $c\,d$ is an unknown quantity, and is equal to F c — F d, therefore, by substitution, $F\,d^2 = \frac{\overline{E\,b^2} \times \overline{F\,c - F\,d}}{a\,b}$, or $\overline{F d^2} \times \frac{\overline{E\,b^2}}{a\,b} \times \overline{F\,d} = \frac{E\,b^2 \times F\,c}{a\,b}$, which is evidently a quadratic equation, which, after reduction, becomes $F\,d = \sqrt{\frac{\overline{E\,b^2} \times F\,c}{a\,b} + \frac{\overline{E\,b^4}}{4}} - \frac{E\,b^2}{2}$.

A small inclination of the jet increases its altitude.

240. From a comparison of the 5th and 6th columns of the table, it appears that a small inclination of the jet, to a vertical line, makes it rise higher than when it ascends exactly vertical;[1] but even then it still falls short of the height of the reservoir. When the water first escapes from the adjutage, it generally springs higher than the reservoir; but this effect is merely momentary, as the jet instantly subsides, and continues at the altitudes exhibited in the foregoing tables. The great size of the jet at its first formation, and its subsequent diminution, have been ascribed by some philosophers to the elasticity of the air which follows the water in its passage through the orifice; but it is obvious, that this air, which moves along with the fluid, can never give it an impulsive force. In order to explain this phenomenon, let us suppose the adjutage to be stopped; then the air which the water drags along with it, will lodge itself at the extremity of the adjutage, so that there will be no water contiguous to the body which covers the orifice. As soon as the cover is removed from the adjutage, the imprisoned air escapes; the water immediately behind it rushes into the space which it leaves, and thus acquires in the tube a certain velocity which increases at the orifice in the ratio of the area of the section of the tube to the area of the section of the orifice (art. 189, note). When the orifice is small in comparison with the tube, the velocity of the issuing fluid must be considerable, and will raise it higher than the reservoir. But as the jet is resisted by the air, and retarded by the descending fluid, its altitude diminishes, and the simple pressure of the fluid becomes the only permanent source of its velocity. The preceding phenomenon was first noticed by Toricellius,[2] who seems to ascribe the diminution in the altitude of the jet to the gravity of the descending particles.

The jet rises higher than the reservoir at its commencement.

241. The following table exhibits all that is necessary in the formation of jets. The two first columns are taken from Mariotte,[3] and shew the altitude of the reservoir requisite to producing a jet of a certain height. The third column contains, in Paris pints, 36 of which are equal to a cubic foot, the quantity of water discharged in a minute by an orifice six lines in diameter. The fourth column, computed from the hypothesis in art. 238 contains the diameters of the horizontal tubes for an adjutage six lines in diameter, relative to the altitudes in the second column. The thickness of the horizontal tubes will be determined in a subsequent section.

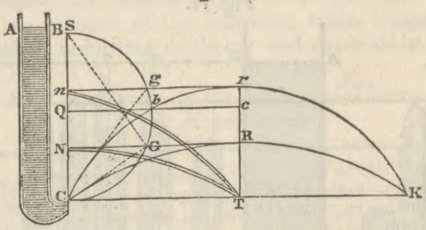
242. We have already seen that jets do not rise to the heights of their reservoirs; and have remarked that the difference between theory and experiment arises from the friction at the orifice, and the resistance of the air. The diminution of velocity produced by friction is very small, and the resistance of the air is a very inconsiderable source of retardation, unless when the jet rises to a great altitude. We must seek, therefore, for another cause of obstruction to the rising jet, which, when combined with these, may be adequate to the effect produced. Wolfius[1] has very properly ascribed the diminution in the altitude of the jet to the gravity of the falling water. When the velocity of the foremost particles is completely spent, those immediately behind, by impinging against them, lose their velocity, and, in consequence of this constant struggle between the ascending and descending fluid, the jet continues at an altitude less than that of the reservoir. Hence we may discover the reason why an inclination of the jet increases its altitude; for the descending fluid falling a little to one side does not encounter the rising particles, and therefore permits them to reach a greater altitude than when their ascension is in a vertical line. Wolfius observes, in proof of his remark that the diminution is occasioned also by the weight of the *ascending* fluid, that mercury rises to a less height than water: but this cannot be owing to the greater specific gravity of mercury; for though the weight of the mercurial particles is greater than that of water, yet the momentum with which they ascend is proportionally greater, and therefore the resistance which opposes their tendency downwards, has the same relation to their gravity, as the resistance in the case of water has to the weight of the aqueous particles.

Experiments on oblique jets by Bossut.

243. The theory of oblique jets has already been discussed in Prop. IX. art. 200. The two following experiments are given by Bossut. When the height NS of the reservoir AB (fig. 72) was 9 feet, and the diameter of the

Experiments on the Motion of Fluids.

Fig. 72.



adjutage at N, 6 lines, a vertical abscissa CN of 4 feet 3 inches and 7 lines, answered to a horizontal ordinate CT of 11 feet 3 inches and 3 lines. When the altitude NS of the reservoir was 4 feet, the adjutage remaining the same, a vertical abscissa CN of 4 feet 3 inches and 7 lines, corresponded with a horizontal ordinate CT of 8 feet 2 inches and 8 lines. The real amplitudes, therefore, are less than those deduced from theory; and both are very nearly as the square roots of the altitudes of the reservoirs. Hence, to find the amplitude of a jet when the height of the reservoir is 10 feet, and the vertical abscissa the same, we have $\sqrt{9}$ feet : $\sqrt{16}$ feet $=$ 11 feet 3 inches 3 lines : 15 feet 4 lines, the amplitude of the jet required. This rule, however, will apply only to small reservoirs; for when the jets enlarge, the curve which they describe cannot be determined by theory, and therefore the relation between the amplitudes and the heights of the reservoirs must be uncertain.

By Michelotti and Venturi.

244. The following experiments on oblique jets were performed by MM. Michelotti and Venturi. When the height of the adjutage above a horizontal plane was 19.33 inches, the amplitude of projection, according to Michelotti, was 23.2 inches, with a simple orifice, and 20 inches with an additional tube. Venturi found, that when the height of the water in the reservoir was $32\frac{1}{2}$ inches, and that of the adjutage above a horizontal plane 54 inches, the amplitude of projection was $81\frac{1}{2}$ inches with a simple orifice, and 69 inches with an additional tube.

SECT. V. *Experiments on the Motion of Water in Conduit Pipes.*

Motion of water in conduit pipes.

245. The experiments of the Chevalier de Buat will be given at great length in the article WATER-WORKS. That the reader, however, may be in possession of every thing valuable on a subject of such public importance, we shall at present give a concise view of the experiments of Couplet, Bossut, and Prony, and of the practical conclusions which they authorize us to form.

246. It must be evident to every reader, that, when water is conducted from a reservoir by means of a long horizontal pipe, the velocity with which the water enters the pipe will be much greater than the velocity with which it issues from its farther extremity; and that, if the pipe has various flexures or bendings, the velocity with which the water leaves the pipe will be still farther diminished. The difference, therefore, between the initial velocity of the water, and the velocity with which it issues, will increase with the length of the pipe and the number of its flexures. By means of the theory, corrected by the preceding experiments, it is easy to determine with great accuracy the initial velocity of the water, or that with which it enters the pipe; but on the obstructions which the fluid experiences in its progress through the pipe, and on the causes of these obstructions, theory throws but a feeble light. The experiments of Bossut afford much instruction

[1] *Wolfii Opera Mathemat.* tom. i. p. 802, schol. 4.

xperi- nts on t Motion Fluids.

on this subject; and it is from them that we have arranged the following table, containing the quantities of water discharged by pipes of different lengths and diameters, compared with the quantities discharged from additional tubes.

Experiments on the Motion of Fluids.

TABLE XIII. *Containing the Quantities of Water discharged by Conduit Pipes of different lengths and diameters, compared with the Quantities discharged from additional tubes inserted in the same Reservoir.*

Constant altitude of the water in the reservoir above the axis of the tube.	Length of the conduit pipes.	Quantity of water discharged in a minute by an additional tube. (Tube and pipe 16 lines diam.) duc- ns from prece- g table.

247. The third column of the preceding table contains the quantity of water discharged through an additional cylindrical tube 16 lines in diameter, or the quantity discharged from the reservoir into a conduit pipe of the same diameter; and the fourth column contains the quantity discharged by the conduit pipe. The fifth column, therefore, which contains the ratio between these quantities, will also contain the ratio between the velocity of the water at its entrance into the conduit pipe, which we shall afterwards call its initial velocity, and its velocity when it issues from the pipe, which shall be denominated its final velocity; for the velocities are as the quantities discharged, when the orifices are the same. The same may be said of the 6th, 7th, and 8th columns, with this difference only, that they apply to a cylindrical tube and a conduit pipe 24 lines in diameter.

use of retar- ion of ter in ving es.

248. By examining some of the experiments in the foregoing table, it will appear that the water sometimes loses $\frac{8}{10}$ths of its initial velocity. The velocity thus lost is consumed by the friction of the water on the sides of the pipe, as the quantities discharged, and consequently the velocities diminish when the length of the pipe is increased. In simple orifices, the friction is in the inverse ratio of their diameter; and it appears from the table, that the velocity of the water is more retarded in the pipe 16 lines in diameter, than in the other, which has a diameter of 24 lines. But though the velocity decreases when the length of the tube is increased, it by no means decreases in a regular arithmetical progression, as some authors have maintained. This is obvious from the table, from which it appears, that the differences between the quantities discharged, which represent also the differences between the velocities, always *decrease*, whereas the differences would have been *equal*, had the velocities decreased in an arithmetical progression. The same truth is capable of a physical explanation. If every filament of the fluid rubbed against the sides of the conduit pipe, then, since in equal times they all experience the same degree of friction, the velocities must diminish in the direct ratio of the lengths of the tubes, and will form a regular arithmetical progression, of which the first term will be the final, and the last the initial velocity of the water. But it is only the lateral filaments that are exposed to friction. This retards their motion; and the adjacent filaments which do not touch the pipe, by the adhesion to those which do touch it, experience also a retardation, but in a less degree, and go on with the rest, each filament sustaining a diminution of velocity inversely proportional to its distance from the sides of the pipe. The lateral filaments alone, therefore, provided they always remain in contact with the sides of the pipe, will have their velocities diminished in arithmetical progression, while the velocities of the central filaments will not decrease in a much slower progression; consequently, the mean velocity of the fluid, or that to which the quantities discharged are proportional, will decrease *less* rapidly than the terms of an arithmetical progression.

249. When the altitude of the reservoir was two feet, the diminution of discharge, and consequently of velocity, was greater than when the height of the reservoir was only one foot. The cause of this is manifest. Friction increases with the velocity, because a greater number of obstructions are encountered in a certain time, and the velocities are as the square roots of the altitudes; therefore friction must also be as the square roots of the altitudes of the reservoir. On some occasions Coulomb found that the friction of solid bodies diminished with an augmentation of velocity, but there is no ground for supposing that this takes place in the case of fluids.

The retardation diminishes as the altitude of the reservoir increases.

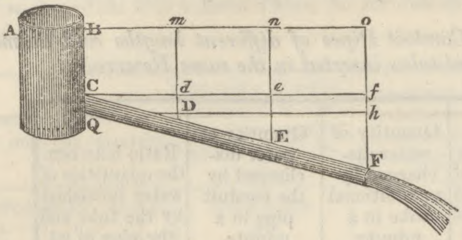
250. When the pipe is inclined to the horizon, as CGF, the water will move with a greater velocity than in the horizontal tube C G hf. In the former case, the relative gravity of the water, which is to its absolute gravity as Ff to Cf, or as the height of the inclined plane to its length, accelerates its motion along the tube. But this acceleration takes place only when the inclination is considerable; for if the angle which the direction of the pipe forms with the horizon were no more than one degree, the retardation of friction would completely counterbalance the accel-

In inclined pipes the velocity of the fluid is increased by its relative gravity. Fig. 73.

Experiments on the Motion of Fluids.

leration of gravity. Thus when the pipe CF, 16 lines in

Fig. 73.



diameter, was 177 feet, and was divided into three equal parts in the points D and E, so that CD was 59 feet, CE 118 feet; and when CF was to F*f* as 2124 to 241, the quantity of water discharged at F was 5795 cubic inches in a minute, the quantity discharged at E was 5801 cubic inches in a minute, and the quantity at D 5808 cubic inches. The quantities discharged therefore, and consequently the velocities, decreased from C to F; whereas if there had been no friction, and no adhesion between the aqueous particles, the velocities would have increased along the line CF in the subduplicate ratio of the altitudes CB, D *m*, E *n*, and F *o*; AB being the surface of the water in the reservoir. The preceding numbers, representing the quantities discharged at FE and D, decrease very slowly; consequently, by increasing the relative gravity of the water, that is, by inclining the tube more to the horizon, the effects of friction may be exactly counterbalanced. This happens when the angle *f* CF is about 6° 31′, or when F *f* is the eighth or ninth part of CF. The quantities discharged at CDE and F will be then equal, and friction will have consumed the velocity arising from the relative gravity of the included water.

Friction destroys this increase of velocity when the inclination of the pipe is 6° 31′.

251. In order to determine the effects produced by flexures or sinuosities in conduit pipes, M. Bossut made the following experiments.

Table XIV. *Shewing the Quantities of Water discharged by rectilineal and curvilineal leaden Pipes, 50 feet long, and 1 inch in diameter.*

Fig. 74.

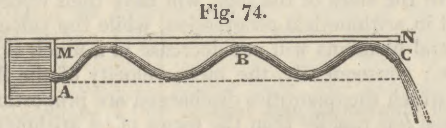

Fig. 75.

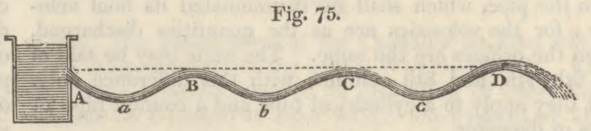

252. 1. The two first experiments of the preceding table shew, that the quantities of water discharged diminish as the altitude of the reservoir. This arises from an increase of velocity, which produces an increase of friction.

2. The four first experiments shew, that a curvilineal pipe, in which the flexures lie horizontally, discharges less water than a rectilineal pipe of the same length. The friction being the same in both cases, this difference must arise from the impulse of the fluid against the angles of the tube; for if the tube formed an accurate curve, it is demonstrable that the curvature would not diminish the velocity of the water.

3. By comparing the 1st and 5th, and the 2d and 6th, experiments, it appears that, when the flexures are vertical, the quantity discharged is diminished. This also arises from the imperfection of curvature.

4. It appears, from a comparison of the 3d and 5th, with the 4th and 6th experiments, that when the flexures are vertical, the quantity discharged is less than when they are horizontal. In the former case, the motion of the fluid arises from the central impulsion of the water, retarded by its gravity in the ascending parts of the pipe, and accelerated in the descending parts; whereas the motion, in the latter case, arises wholly from the central impulsion of the fluid. To these points of difference the diminution of velocity may somehow or other be owing.

When a large pipe has a number of contrary flexures, the air sometimes mixes with the water, and occupies the highest parts of each flexure, as at B and C, fig. 75. By this means the velocity of the fluid is greatly retarded, and the quantities discharged much diminished. This ought to be prevented by placing small tubes at B and C, having a small valve at their top. Fig. 75.

253. A set of valuable experiments, on a large scale, were made by M. Couplet upon the motion of water in conduit pipes, and a detailed account of them is given in the Memoirs of the Academy for 1732, in his paper entitled *Des Recherches sur le Mouvement des Eaux dans les Tuyaux de conduite.* These experiments are combined with those of the Abbé Bossut in the following table, which gives a distinct view of all that they have done on this subject, and will be of great use to the practical engineer.

Experiments of Couplet.

xperi-ents on e Motion Fluids.

Experiments on the Motion of Fluids.

pplica-ion and se of the receding able.

254. In order to shew the application of the preceding results, let us suppose that a spring, or a number of springs combined, furnishes 40,000 cubic inches of water in one minute; and that it is required to conduct it to a given place 4 feet below the level of the spring, and so situated that the length of the pipe must be 2400 feet. It appears from Table VI. art. 226, that the quantity of water furnished in a minute by a short cylindrical tube, when the altitude of the fluid in the reservoir is 4 feet, is 7070 cubic inches; and since the quantities furnished by two cylindrical pipes under the same altitude of water are as the squares of their diameters, we shall have by the following analogy the diameter of the tube necessary for discharging 40,000 cubic inches in a minute; $\sqrt{70720} : \sqrt{40000} = 12$ lines or 1 inch : $28.\frac{1}{2}$ lines, the diameter required. But by comparing some of the experiments in the preceding table, it appears that, when the length of the pipe is nearly 2400 feet, it will admit only about one-eighth of the water, that is, about 5000 cubic inches. That the pipe, however, may transmit the whole 40,000 cubic inches, its diameter must be increased. The following analogy, therefore, will furnish us with this new diameter; $\sqrt{5000} : \sqrt{40000} = 28.54$ lines : 80.73 lines, or 6 inches $8\frac{7}{10}$ lines, the diameter of the pipe which will discharge 40,000 cubic inches of water when its length is 2400 feet.

255. The following experiments were made by M. Bossut of Mezières in October 1779; and they are highly interesting, as they were made on the water discharged from the public and private fountains of that city.

Experiments on the Motion of Fluids.

Experiments on the pressure sustained by pipes.

SECT. VI. *Experiments on the Pressure exerted upon Pipes by the water which flows through them.*

256. The pressure exerted upon the sides of conduit pipes by the included water has been already investigated theoretically in Prop. X. Part II. The only way of ascertaining by experiment the magnitude of this lateral pressure is to make an orifice in the side of the pipe, and find the quantity of water which it discharges in a given time. This lateral pressure is the force which impels the water through the orifice; and therefore the quantity discharged, or the effect produced, must be always proportional to that pressure as its producing cause, and may be employed to represent it. The following table, founded on the experiments of Bossut, contains the quantities of water discharged from a lateral orifice about $3\frac{1}{4}$ lines in diameter, according to theory and experiment.

TABLE XVII. *Containing the Quantities discharged by a Lateral Orifice, or the Pressures on the Sides of Pipes, according to Theory and Experiment.*

Altitude of the Water in the Reservoir.	Length of the Conduit Pipe.	Quantities of Water discharged in 1 Minute, according to Theory.	Quantities of Water discharged in 1 Minute, according to Experiment.
Feet.	Feet.	Cubic Inches.	Cubic Inches.
1	30	176	171
1	60	186	186
1	90	190	190
1	120	191	191
1	150	192	193
1	180	193	194
2	30	244	240
2	60	259	256
2	90	264	261
2	120	267	264
2	150	268	265
2	180	269	266

It appears from the preceding table, that the real lateral pressure in conduit pipes differs very little from that which is computed from the formula; but in order that this accordance may take place, the orifice must be so perforated, that its circumference is exactly perpendicular to the direction of the water, otherwise a portion of the water dis-xperi-ents on Motion Fluids.

charged would be owing to the direct motion of the included fluid.

257. As pipes are exposed to forces besides those arising from the included water, they must be made much stronger than the preceding experiments would seem to require. The thicknesses of iron and leaden pipes used in France in the time of Bossut, are given in the following table.

Iron Pipes.		Leaden Pipes.	
Diameter.	Thickness.	Diameter.	Thickness.
Inches.	Lines.	Inches.	Lines.
1	1	1	$2\frac{1}{2}$
2	3	$1\frac{1}{2}$	3
4	4	2	4

12	8	7	8

Sect. VII. *Experiments on the Motion of Water in Canals.*

Experiments on the Motion of Fluids.

Experiments on the velocity of water in horizontal canals.

258. Among the numerous experiments which have been made on this important subject, those of the Abbé Bossut seem entitled to the greatest confidence. His experiments were made on a rectangular canal 105 feet long, 5 inches broad at the bottom, and from 8 to 9 inches deep. The orifice which transmitted the water from the reservoir into the canal was rectangular, having its horizontal base constantly five inches, and its vertical height sometimes half an inch, and at other times an inch. The sides of this orifice were made of copper, and rising perpendicularly from the side of the reservoir, they formed two vertical planes parallel to each other. This projecting orifice was fitted into the canal, which was divided into 5 equal parts of 21 feet each, and also into 3 equal parts of 35, and the time was noted which the water employed in reaching these points of division. The arrival of the water at these points was indicated by the motion of a very small water wheel placed at each, and impelled by the stream. When the canal was horizontal, the following results were obtained.

Table XVIII. *Containing the Velocity of Water in a Rectangular Horizontal Canal* 105 *feet long, under different Altitudes of Fluid in the Reservoir.*

Altitude of the water in the reservoir.	Ft. In. 11 8	Ft. In. 7 8	Ft. In. 3 8	Ft. In. 11 8	Ft. In. 7 8	Ft. In. 3 8	Space run through by the water.
Vertical breadth of the orifice.	$\frac{1}{2}$ an inch.	$\frac{1}{2}$ an inch.	$\frac{1}{2}$ an inch.	1 inch.	1 inch.	1 inch.	Feet.
Time in which the number of feet in column seventh are run through by the water.	2″	3″—	3″+	2″	2″+	3″—	21
	5—	7	9	4	5	6+	42
	10—	13—	17+	7	9	11+	63
	16—	20—	27+	11	14	18+	84
	23+	28+	38+	$16\frac{1}{4}$	20	26	105

Deductions from the foregoing experiments.

259. It appears from column 1st, that the times successively employed to run through spaces of 21 feet each, are as the numbers 2, 3—, 5, 6, 7+, which form nearly an arithmetical progression, whose terms differ nearly by 1, so that by continuing the progression we may determine very nearly the time in which the fluid would run through any number of feet not contained in the 7th column. The same may be done with the other columns of the table.

If we compute theoretically the time which the water should employ in running through the whole length of the canal, or 105 feet, we shall find, that under the circumstances for each column of the preceding table the times, reckoning from the first column, are 6″.350, 7″.834, 11″.330, 6″.350, 7″.834, 11″.330. It appears, therefore, by comparing these times with those found by experiment, that the velocity of the stream is very much retarded by friction, and that this retardation is less as the breadth of the orifice is increased; for since a greater quantity of water issues in this case from the reservoir, it has more power to overcome the obstacles which obstruct its progress. The signs + and — affixed to the numbers in the preceding table, indicate that these numbers are a little too great or too small.

Experiments on the velocity of water in inclined canals.

260. The following experiments were made on inclined canals with different declivities, and will be of great use to the engineer. The inclination of the canal is the vertical distance of one of its extremities from a horizontal line which passes through its other extremity.

Experiments on the Motion of Fluids.

	Time in which the number of feet in the last col. is run through by the water.						

The velocity of the first portion of water that issues from the reservoir is less than that of the established current.

261. In the preceding experiments, the velocity of the first portion of water that issues from the reservoir was only observed; but when the current is once established, and its velocity permanent, it moves with greater rapidity, and there is always a fixed proportion between the velocity of the first portion of water and the permanent velocity of the established current. The cause of this difference Bossut does not seem to have thoroughly comprehended, when he ascribes it to a diminution of friction when the velocity becomes permanent. The velocity of the first portion of water that issues from the reservoir was measured by its arrival at certain divisions of the canal, consequently the velocity thus determined was the *mean* velocity of the water. The velocity of the established current, on the contrary, was measured by light bodies floating upon its surface, at the centre of the canal, therefore the velocity thus determined was the *superficial* velocity of the stream. But the velocity of the superficial central filaments must be greatest of all, because, being at the greatest distance from the sides and bottom of the canal, they are less affected by friction than any of the adjacent or inferior filaments, and are not retarded by the weight of any superincumbent fluid. The *superficial* velocity of the current must, of consequence, be greater than its *mean* velocity, or, in other words, the velocity of the established current must exceed the velocity of the first portion of water. The following table contains the experiments of Bossut on this subject, the canal being of the same size as in the former experiments, but 600 feet long, and its inclination one-tenth of the whole, or 59.702 feet.

xperi-ents on Motion Fluids.

Sect. VIII. *On the Influence of Heat on the Motion of Fluids.*

Experiments on the Motion of Fluids.

The common theory of the motion of fluids defective in not considering the temperature of the water employed.

262. In all the experiments related in this chapter, and in those of the Chevalier Buat, which are given in the article Water-*Works*, the temperature of the water employed has never been taken into consideration. That the fluidity of water is increased by heat can scarcely admit of a doubt. Professor Leslie, in his ingenious paper on Capillary Action, has proved by experiment that a jet of warm water will spring much higher than a jet of cold water, and that a syphon which discharges cold water only by drops, will discharge water of a high temperature in a continued stream. A similar fact was observed by the ancients. Plutarch[1], in particular, assures us, that the clepsydræ or water clocks went slower in winter than in summer, and he seems to attribute this retardation to a diminution of fluidity. It is therefore obvious, that warm water will issue from an aperture with greater velocity than cold water, and that the quantities of fluid discharged from the same orifice, and under the same pressure, will increase with the temperature of the fluid. Hence we may discover the cause of the great discrepancy between the experiments of different philosophers on the motion of fluids. Their experiments were performed in different climates and at different seasons of the year; and, as the temperature of the water would be variable from these and from other causes, a variation in their results was the inevitable consequence.

Warm water moves faster than cold water.

Experiments of De Buat.

263. M. de Buat and M. Girard are the only persons who have made experiments on this interesting subject. M. de Buat employed in his experiments tubes of a large diameter, and hence the effects of heat were not very conspicuous. The following table contains a general view of the results which he obtained:

Table XXI. *Containing Du Buat's Experiments on the Motion of different Fluids, at different degrees of Temperature, in Tubes of Glass.*

Names of the Fluids.	Diameter and length of the Pipe.	Head of Water above the top of the tube.	Height of the expense in a minute expressed in inches.	Velocity in a second in inches.	Degrees of Heat above the freezing point.

Mercury		0.0555	0.0000	0.000	10 to 12
Alcohol .	Horizontal tube 1½ line in diameter, and 34.16666 inches long	9.292	1.125	10.402	12

[1] Ελαυνѕσα γαρ ἡ ψυχροτης το ὑδωρ ποιει βαρυ και σωματῶδες, ὡς ἐστιν ἐν ταις κλεψυδραις καταμαθειν, βραδιον γαρ ἑλκѕσι χειμωνος ἡ θερѕς. *Aquam enim impellens frigus gravem facit et crassum, quod in clepsydris licet observare ; tardius enim trahunt hyeme quam æstate.*

Plutarch, *Quæst. Natural.*

Hence our author concludes that the velocity of water diminishes as its temperature approaches to that of the freezing point, and *vice versa;* that salt water has a less velocity than rain water, that alcohol runs slower than water, and mercury more rapidly.

Experiments of Girard.

264. The general result of M. Girard's experiments has been already given in the History of HYDRODYNAMICS. His experiments were made with copper tubes of exactly the same internal diameter, and drawn upon steel maundrils; and he employed two sets of these tubes of different diameters. The first set consisted of tubes, whose length was *two* decimeters, and diameter 2.96 millimetres, and they screwed into each other so as to form tubes of various lengths, from 20 to 222 centimetres. The second set consisted of smaller tubes, whose diameter was 1.83 millimetres. These tubes were then fixed horizontally in the sides of a reservoir, which was a cylinder of white iron 25 centimetres in diameter, and 5 decimetres high. The reservoir was kept full by the usual contrivances; and the water discharged by the tube subjected to trial, was received into a copper vessel horizontally, whose capacity had been accurately ascertained. The filling of the vessel was indicated by the instant when the water which it contained had wetted equally a plate of glass which covered almost the whole of its surface, and the time employed to fill this vessel was measured with great accuracy. The temperature of the water was also carefully noted. The results thus obtained amounted to 1200, and were arranged by M. Girard into thirty-four tables, according to the different circumstances of the experiment. When the capillary tube has such a length, that the term proportional to the square of the velocity disappears in the general formula, the velocity with which the fluid is discharged, is affected in a very singular manner by a variation of temperature. If the velocity is expressed by 10, when the temperature is 0° of the centigrade thermometer, the velocity will be so great as 42; or increased more than four times when the temperature amounts to 85° centigrade. When the length of the capillary tube is below the above mentioned limit, a variation of temperature exercises but a slight influence upon the velocity of the issuing fluid. If the length of the adjutage, for example, is 55 millimetres, and if the velocity is represented by 10 at 5° of the centigrade thermometer, it will be represented only by 12 at a temperature of 87°. In conduit pipes of the ordinary diameter, a change of temperature produces almost no perceptible change in the velocity of efflux. M. Girard also found, that the quantity of water discharged by capillary tubes, varied not only with the fluids which were used, but with the nature of the solid substance of which the tubes were composed.

On the Resistance of Fluids.

CHAPTER III.—ON THE RESISTANCE OF FLUIDS.

Reference to the article RESISTANCE *of Fluids.*

265. In the article RESISTANCE *of Fluids*, the reader will find that important subject treated at great length. The researches of preceding philosophers are there given in full detail; their different theories are compared with experiments, and the defects of these minutely considered. Since that article was composed, this intricate subject has been investigated by other writers, and though they have not enriched the science of hydraulics with a legitimate theory of the resistance of fluids, the results of their labours cannot fail to be interesting to every philosopher.

Researches of Coulomb.

266. The celebrated Coulomb has very successfully employed the principle of torsion, to determine the cohesion of fluids, and the laws of their resistance in very slow motions. His experiments are new, and were performed with the greatest accuracy; and the results which he obtained were perfectly conformable to the deductions of theory. We shall therefore endeavour to give the reader some idea of the discoveries which he has made.

267. When a body is struck by a fluid with a velocity exceeding eight or nine inches per second, the resistance has been found proportional to the square of the velocity, whether the body in motion strikes the fluid at rest, or the body is struck by the moving fluid. But when the velocity is so slow as not to exceed four-tenths of an inch in a second, the resistance is represented by two terms, one of which is proportional to the simple velocity, and the other to the square of the velocity. The first of these sources of resistance arises from the cohesion of the fluid particles which separate from one another, the number of particles thus separated being proportional to the velocity of the body. The other cause of resistance is the inertia of the particles, which, when struck by the fluid, acquire a certain degree of velocity proportional to the velocity of the body; and as the number of these particles is also proportional to that velocity, the resistance generated by their inertia must be proportional to the square of the velocity.

Opinions Newton, Bernoull & Grave ende.

268. When Sir Isaac Newton[1] was determining the resistance which the air opposed to the oscillatory motion of a globe in small oscillations, he employed a formula of three terms, one of them varying as the quare of the velocity, the second as the $\frac{3}{2}$ power of the velocity, and the third as the simple velocity; and in another part of the work he reduces the formula to two terms, one of which is as the square of the velocity, and the other constant. D. Bernoulli[2] also supposes the resistance to be represented by two terms, one as the square of the velocity, and the other constant. M. Gravesende[3] has found that the pressure of a fluid in motion against a body at rest, is partly proportional to the simple velocity, and partly to the square of the velocity. But when the body moves in a fluid at rest, he found[4] the resistance proportional to the square of the velocity, and to a constant quantity. When the *body in motion, therefore, meets the fluid at rest*, these three philosophers have agreed, that the formula which represents the resistance of fluids consists of two terms, one of which is as the square of the velocity, and the other constant. The experiments of Coulomb, however, incontestably prove, that the pressure which the moving body in this case sustains, is represented by two terms, one proportional to the simple velocity, and the other to its square, and that if there is a constant quantity, it is so very small as to escape detection.

Appara employ in Coulomb's perime Fig. 7

269. In order to apply the principle of torsion to the resistance of fluids, M. Coulomb made use of the apparatus represented in fig. 76. On the horizontal arm LK, which may be supported by a vertical stand, is fixed the small circle *fe*, perforated in the centre, so as to admit the cylindrical pin *ba*. Into a slit in the extremity of this pin is fastened, by means of a screw, the brass wire *ag*, whose force of torsion is to be compared with the resistance of the fluid; and its lower extremity is fixed in the same way into a cylinder of copper *gd*, whose diameter is about four tenths of an inch. The cylinder *gd* is perpendicular to the disc DS, whose circumference is divided into 480 equal

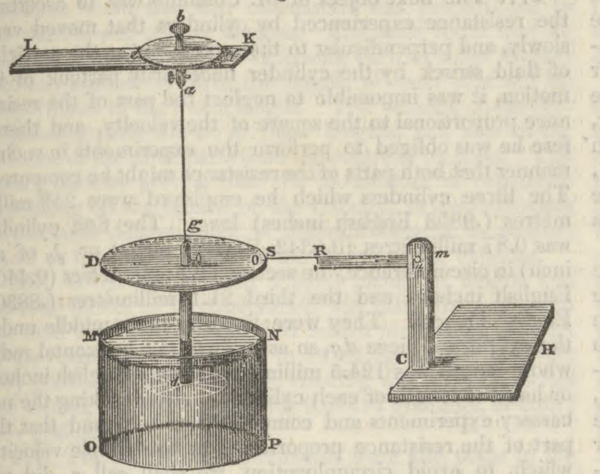
parts. When this horizontal disc is at rest, which happens when the torsion of the brass wire is nothing, the fixed index

Fig. 76.



RS is placed upon the point 0, the zero of the circular scale. The small rule Rm may be elevated or depressed at pleasure round its axis n, and the stand GH which supports it may be brought into any position round the horizontal disc. The lower extremity of the cylinder gd is immersed about two inches in the vessel of water MNOP, and to the extremity d is attached the planes, or the bodies whose resistance is to be determined when they oscillate in the fluid by the torsion of the brass wire. In order to produce these oscillations, the disc DS, supported by both hands, must be turned gently round to a certain distance from the index, without deranging the vertical position of the suspended wire. The disc is then left to itself; the force of torsion causes it to oscillate, and the successive diminutions of these oscillations are carefully observed. A simple formula gives in weights the force of torsion that produces the oscillations; and another formula well known to geometers, determines (by an approximation sufficiently accurate in practice), by means of the successive diminution of the oscillations compared with their amplitude, what is the law of the resistance, relative to the velocity, which produces these diminutions.

270. The method employed by Coulomb, in reducing his experiments, is similar to that adopted by Newton and other mathematicians, when they wished to determine the resistance of fluids, from the successive diminutions of the oscillations of a pendulum moving in a resisting medium; but is much better fitted for detecting the small quantities which are to be estimated in such researches. When the pendulum is employed, the specific gravity of the body, relative to that of the fluid, must be determined; and the least error in this point leads to very uncertain results. When the pendulum is in different points of the arc in which it oscillates, the wire or pendulum rod is plunged more or less in the fluid; and the alterations which may result from this are frequently more considerable than the small quantities which are the object of research. It is only in small oscillations, too, that the force which brings the pendulum from the vertical, is proportional to the angle which the pendulum rod, in different positions, forms with this vertical line; a condition which is necessary before the formulæ can be applied. But small oscillations are attended with great disadvantages; and their successive diminutions cannot be determined but by quantities which it is difficult to estimate exactly, and which are changed by the smallest motion either of the fluid in the vessel, or of the air in the chamber. In small velocities, the pendulum rod experiences a greater resistance at the point of floatation than at any other part. This resistance, too, is very changeable; for the water rises from its level along the pendulum rod to greater or less heights, according to the velocity of the pendulum.

On the Resistance of Fluids.

Advantages of comparing the resistance of fluids with the force of torsion.

271. These and other inconveniences which might be mentioned, are so inseparable from the use of the pendulum, that Newton and Bernoulli have not been able to determine the laws of the resistance of fluids in very slow motions. When the resistance of fluids is compared with the force of torsion, these disadvantages do not exist. The body is in this case entirely immersed in the fluid; and as every point of its surface oscillates in a horizontal plane, the relation between the densities of the fluid and the oscillating body has no influence whatever on the moving force. One or two circles of amplitude may be given to the oscillations; and their duration may be increased at pleasure, either by diminishing the diameter of the wire, or increasing its length; or, which may be more convenient, by augmenting the momentum of the horizontal disc. Coulomb, however, found that when each oscillation was so long as to continue about 100 seconds, the least motion of the fluid, or the tremor occasioned by the passing of a carriage, produced a sensible alteration on the results. The oscillations best fitted for experiments of this kind, continued from 20 to 30 seconds, and the amplitude of those that gave the most regular results, was comprehended between 480 degrees, the entire division of the disc, and 8 or 10 divisions reckoned from the zero of the scale. From these observations, it will be readily seen, that it is only in very slow motions that an oscillating body can be employed for determining the resistance of fluids. In small oscillations, or in quick circular motions, the fluid struck by the body is continually in motion; and when the oscillating body returns to its former position, its velocity is either increased or retarded by the motion communicated to the fluid, and not extinguished.

When the velocity is very small, the part of the resistance proportional to the square of the velocity disappears.

272. In the first set of experiments made by Coulomb, he attached to the lower extremity of the cylinder gd a circular plate of white iron, about 195 millimetres in diameter, and made it move so slowly, that the part of the resistance proportional to the square of the velocity wholly disappeared. For if, in any particular case, the portion of the resistance proportional to the simple velocity should be equal to the portion that is proportional to the square of the velocity when the body has a velocity of one-tenth of an inch per second, then, when the velocity is 100-tenths of an inch per second, the part proportional to the square of the velocity will be a hundred times greater than that proportional to the simple velocity; but if the velocity is only the hundredth part of the tenth of an inch per second, then the part proportional to the simple velocity will be 100 times greater than the part proportional to the square of the velocity.

Result of Coulomb's experiments on the resistance of water to a horizontal plate moving round its centre in the plane of its superficies.

273. When the oscillations of the white iron plate were so slow, that the part of the resistance which varies with the second power of the velocity was greatly inferior to the other part, he found, from a variety of experiments, that the resistance which diminished the oscillations of the horizontal plate was uniformly proportional to the simple velocity, and that the other part of the resistance, which follows the ratio of the square of the velocity, produced no sensible change upon the motion of the white iron disc. He also found, in conformity with theory, that the momenta of resistance in different circular plates moving round their centre in a fluid, are as the fourth power of the diameters of these circles; and that, when a circle of 195 millimetres (6.677 English inches) in diameter, moved round its centre in water, so that its circumference had a velocity of 140 millimetres (5.512 English inches) per second, the momentum of resistance which the fluid opposed to its circular motion was equal to one-tenth of a

On the Resistance of Fluids.

gramme (1.544 English troy grains) placed at the end of a lever 143 millimetres (5.63 English inches) in length.

Similar result obtained in clarified oil.

274. M. Coulomb repeated the same experiments in a vessel of clarified oil, at the temperature of 16 degrees of Reaumur. He found, as before, that the momenta of the resistance of different circular discs, moving round their centre in the plane of their superficies, were as the fourth power of their diameters; and that the difficulty with which the same horizontal plate, moving with the same velocity, separated the particles of oil, was to the difficulty with which it separated the particles of water, as 17.5 to 1, which is therefore the ratio that the mutual cohesion of the particles of oil has to the mutual cohesion of the particles of water.

Ratio between the mutual cohesion of the particles of oil, and the mutual cohesion of the particles of water.

The resistance not influenced by the nature of the surface of the moving body.

275. In order to ascertain whether or not the resistance of a body moving in a fluid was influenced by the nature of its surface, M. Coulomb anointed the surface of the white iron plate with tallow, and wiped it partly away, so that the thickness of the plate might not be sensibly increased. The plate was then made to oscillate in water, and the oscillations were found to diminish in the same manner as before the application of the unguent. Over the surface of the tallow upon the plate, he afterwards scattered, by means of a sieve, a quantity of coarse sand which adhered to the greasy surface; but when the plate, thus prepared, was caused to oscillate, the augmentation of resistance was so small, that it could scarcely be appreciated. We may therefore conclude, that the part of the resistance which is proportional to the simple velocity, is owing to the mutual adhesion of the particles of the fluid, and not to the adhesion of these particles to the surface of the body.

Experiments for finding if the resistance is increased by increasing the superincumbent fluid.

276. If the part of the resistance varying with the simple velocity were increased when the white iron plate was immersed at greater depths in the water, we might suppose it to be owing to the friction of the water on the horizontal surface, which, like the friction of solid bodies, should be proportional to the superincumbent pressure. In order to settle this point, M. Coulomb made the white iron plate oscillate at the depth of two centimetres (.787 English inches), and also at the depth of 50 centimetres (19.6855 English inches), and found no difference in the resistance; but as the surface of the water was loaded with the whole weight of the atmosphere, and as an additional load of 50 centimetres of water could scarcely produce a perceptible augmentation of the resistance, M. Coulomb employed another method of deciding the question. Having placed a vessel full of water under the receiver of an air-pump, the receiver being furnished with a rod and collar of leather at its top, he fixed to the hook, at the end of the rod, a harpsichord wire, number 7 in commerce, and suspended to it a cylinder of copper, like gd, fig. 76, which plunged in the water of the vessel, and under this cylinder he fixed a circular plane, whose diameter was 101 millimetres (3.976 English inches). When the oscillations were finished, and consequently the force of torsion nothing, the zero of torsion was marked by the aid of an index fixed to the cylinder. The rod was then made to turn quickly round through a complete circle, which gave to the wire a complete circle of torsion, and the successive diminutions of the oscillations were carefully observed. The diminution for a complete circle of torsion was found to be nearly a fourth part of the circle for the first oscillation, but always the same whether the experiment was made in a vacuum or in the atmosphere. A small pallet 50 millimètres long (1.969 English inches), and 10 millimètres broad (0.3937 English inches), which struck the water perpendicular to its plane, furnished a similar result. We may therefore conclude, that when a submerged body moves in a fluid, the pressure which it sustains, measured by the altitude of the superior fluid, does not perceptibly increase the resistance; and consequently, that the part of this resistance proportional to the simple velocity, can in no respect be compared with the friction of solid bodies, which is always proportional to the pressure.

On the Resistan[ce] of Flui[ds.]

On the re[]sistance [of] cylinder[s] moving perpend[i]cular to their ax[es.]

277. The next object of M. Coulomb was to ascertain the resistance experienced by cylinders that moved very slowly, and perpendicular to their axes; but as the particles of fluid struck by the cylinder necessarily partook of its motion, it was impossible to neglect the part of the resistance proportional to the square of the velocity, and therefore he was obliged to perform the experiments in such a manner that both parts of the resistance might be computed. The three cylinders which he employed were 249 millimetres (.9803 English inches) long. The first cylinder was 0.87 millimètres (0.0342 English inches or $\frac{1}{29}$ of an inch) in circumference, the second 11.2 millimètres (0.4409 English inches), and the third 21.1 millimètres (.88307 English inches). They were fixed by their middle under the cylindrical piece dg, so as to form two horizontal radii, whose length was 124.5 millimètres (.4901 English inches) or half the length of each cylinder. After making the necessary experiments and computations, he found that the part of the resistance proportional to the simple velocity, which, to avoid circumlocution, we shall call r, did not vary with the circumferences of the cylinders. The circumferences of the first and third cylinders were to one another as 24 : 1, whereas the resistances were in the ratio of 3 : 1. The same conclusion was deduced by comparing the experiments made with the first and second cylinder.

The res[ist]ance du[e to] the sim[ple] velocity not pro[por]tional t[o] the circ[um]ference[s of] the cyli[n]ders.

Cause [of] this.

278. In order to explain these results, M. Coulomb very justly supposes, that, in consequence of the mutual adhesion of the particles of water, the motion of the cylinder is communicated to the particles at a small distance from it. The particles which touch the cylinder have the same velocity as the cylinder, those at a greater distance have a less velocity, and at the distance of about one-tenth of an inch the velocity ceases entirely, so that it is only at that distance from the cylinder that the mutual adhesion of the fluid molecules ceases to influence the resistance. The resistance r therefore should not be proportional to the circumference of the real cylinder, but to the circumference of a cylinder whose radius is greater than the real cylinder by one-tenth of an inch. It consequently becomes a matter of importance to determine with accuracy the quantity which must be added to the real cylinder in order to have the radius of the cylinder to which the resistance r is proportional, and from which it must be computed. Coulomb found the quantity by which the radius should be increased to be 1.5 millimetres ($\frac{59}{1000}$ of an English inch), so that the diameter of the augmented cylinder will exceed the diameter of the real cylinder by double that quantity, or $\frac{118}{1000}$ of an inch.

The re[sist]ance d[ue to] the *sim[ple] velocity* propor[tion]al to t[he] circum[fe]rence [of] the cyl[in]ders w[hen] their r[adii] are au[g]mente[d] $\frac{59}{1000}$ o[f an] inch.

The re[sist]ance d[ue to] the *sq[uare] of the* [velo]*city* is [pro]portio[nal] to the [cir]cumfe[r]ences [of] the cy[lin]ders w[hen] their r[adii] are au[g]mente[d] $\frac{11}{1000}$ o[f an] inch.

279. The part of the resistance varying with the square of the velocity, or that arising from the inertia of the fluid, which we shall call R, was likewise not proportional to the circumferences of the cylinder; but the augmentation of the radii amounts in this case only to $\frac{11}{1000}$ of an inch, which is only one-fifth of the augmentation necessary for finding the resistance r. The reason of this difference is obvious; all the particles of the fluid when they are separated from each other oppose the same resistance, whatever be their velocity; consequently as the value of r depends only on the adhesion of the particles, the resistances due to this adhesion will reach to the distance from the cylinder where the velocity of the particles is 0. In comparing the different values of R, the part of the resistance which varies as the square of the velocity, all the particles are supposed to have a velocity equal to that of the cylinder; but as it is only the particles which touch the cylinder that have this velocity, it follows that the augmentation of the diameter necessary for finding R must be less than the augmentation necessary for finding r.

Cause [of] this di[ffer]ence.

the tance uids. ion een sist- and iame- f the lers.

280. In determining experimentally the part of the momentum of resistance proportional to the velocity, by two cylinders of the same diameter, but of different lengths, M. Coulomb found that this momentum was proportional to the third power of their lengths. The same result may be deduced from theory; for supposing each cylinder divided into any number of parts, the length of each part will be proportional to the whole length. The velocity of the corresponding parts will be as these lengths, and also as the distance of the same parts from the centre of rotation. The theory likewise proves, that the momentum of resistance depending on the square of the velocity, in two cylinders of the same diameter but of different lengths, is proportional to the fourth power of the length of the cylinder.

resist- of a cy- r.

281. When the cylinder 0.9803 inches in length, and 0.04409 inches in circumference, was made to oscillate in the fluid with a velocity of 5.51 inches per second, the part of the resistance r was equal to 58 milligrammes, or .8932 troy grains. And when the velocity was 0.3937 inches per second, the resistance r was 0.00414 grammes, or 0.637 troy grains.

lt of reced- xperi- s made l.

282. The preceding experiments were also made in the oil formerly mentioned; and it likewise appeared, from their results, that the mutual adhesion of the particles of oil was to the mutual adhesion of the particles of water as 17 to 1. But though this be the case, M. Coulomb discovered that the quantity by which the radii of the cylinder must be augmented in order to have the resistance r, is the very same as when the cylinder oscillated in water. This result was very unexpected, as the greater adhesion between the particles of oil might have led us to anticipate a much greater augmentation. When the cylinders oscillated both in oil and water with the same velocity, the part of the resistance R produced by the inertia of the fluid particles which the cylinder put in motion, was almost the same in both. As this part of the resistance depends on the quantity of particles put in motion, and not on their adhesion, the resistances due to the inertia of the particles will be in different fluids as their densities. On the Resistance of Fluids.

283. In a subsequent memoir, Coulomb proposes to determine numerically the part of the resistance proportional to the square of the velocity, and to ascertain the resistance of globes with plain, convex, and concave surfaces. He has found in general that the resistance of bodies not entirely immersed in the fluid is much greater than that of bodies which are wholly immersed; and he promises to make further experiments upon this point. We intended on the present occasion to have given the reader a more complete view of the researches of this ingenious philosopher; but these could not well be understood without a knowledge of his investigations respecting the force of torsion, which we have not yet had an opportunity of communicating. In the article MECHANICS, however, we shall introduce the reader to this interesting subject; and may afterwards have an opportunity of making him farther acquainted with those researches of Coulomb, of which we have at present given only a general view. Coulomb promises to extend his researches on the resistance of fluids.

284. The subject of the resistance of fluids has been recently treated by the learned Dr Hutton of Woolwich. His experiments were made in air with bodies of various forms, moving with different velocities, and inclined at various angles to the direction of their motion. The following table contains the results of many interesting experiments. The numbers in the ninth column represent the exponents of the power of the velocity which the resistances in the 8th column bear to each other. Researches of Dr Hutton.

sults of pre- ing ex- iments.

285. From the preceding experiments we may draw the following conclusions: 1. That the resistance is nearly proportional to the surfaces, a small increase taking place when the surfaces and the velocities are great. 2. The resistance to the same surface moving with different velocities, is nearly as the square of the velocity; but it appears from

On the Resistance of Fluids.

the 9th column that the exponent increases with the velocity. 3. The round and sharp ends of solids sustain a greater resistance than the flat ends of the same diameter. 4. The resistance to the base of the hemisphere is to the resistance on the convex side, or the whole sphere, as $2\frac{1}{3}$, to 1, instead of 2 to 1, as given by theory. 5. The resistance on the base of the cone is to the resistance on the vertex nearly as $2\frac{3}{10}$ to 1; and in the same ratio is radius to the sine of half the angle at the vertex. Hence in this case the resistance is directly as the sine of the angle of incidence, the transverse section being the same. 6. The resistance of the base of a hemisphere, the base of a cone, and the base of a cylinder, are all different, though these bases be exactly equal and similar.

286. The following table contains the resistance sustained by a globe 1.965 inches in diameter. The fourth column is the quotient of the resistance by experiment, divided by the theoretical resistance.

Experiments with a Globe 1.965 inches in diameter.

287. It appears from a comparison of the 2d, 3d, and 4th columns, that when the velocity is small, the resistance by experiment is nearly equal to that deduced from theory: but that as the velocity increases, the former gradually exceeds the latter till the velocity is 1300 feet per second, when it becomes twice as great. The difference between the two resistances then increases, and reaches its maximum between the velocities of 1600 and 1700 feet. It afterwards decreases gradually as the velocity increases, and at the velocity of 2000 the resistance by experiment is again double of the theoretical resistance. By considering the numbers in column 5th, it will be seen, that in slow motions the resistances are nearly as the square of the velocities; that this ratio increases gradually, though not regularly, till at the velocity of 1500 or 1600 feet it arrives at its maximum. It then gradually diminishes as the velocity increases.

Conclusions similar to these were deduced from experiments made with globes of a larger size.

288. The following table contains the resistance of a plane inclined at various angles, according to experiment, and according to a formula deduced from the experiments.

TABLE III. *Containing the Resistances to a plane inclined at various Angles to the Line of its Motion.*

1	2	3	4

289. The plane with which the preceding experiments were performed was 32 square inches, and always moved with a velocity of 12 feet per second. The resistances which this plane experienced are contained in column 2d. From the numbers in that column Dr Hutton deduced the formula $.84s^{1.842}c$, where s is the sine, and c the cosine of the angles of inclination in the first column. The resistances computed from this formula are contained in column 3d, and agree very nearly with the resistances deduced from experiment. The 4th column contains the sines of the angles in the first column to a radius .84, in order to compare them with the resistances which have obviously no relation either to the sines of the angles or to any power of the sines. From the angle of 0 to about 60° the resistances are less than the sines; but from 60° to 90° they are somewhat greater.

Researches of Mr Vince.

290. The experiments of Mr Vince were made with bodies at a considerable depth below the surface of water; and he determined the resistance which they experienced, both when they moved in the fluid at rest, and when they received the impulse of the moving fluid. In the experiments contained in the following table, the body moved in the fluid with a velocity of 0.66 feet in a second. The angles at which the planes struck the fluid are contained in the first column. The second column shews the resist-

ance by experiment in the direction of their motion in troy ounces. The third column exhibits the resistance by theory, the perpendicular distance being supposed the same as by experiment. The fourth column shews the power of the sine of the angle to which the resistance is proportional, and was computed in the following manner. Let s be the sine of the angle, radius being 1, and r the resistance at that angle. Suppose r to vary as s^m, then we have $r^m : s^m = 0.2321 : r$; hence $s^m = \frac{1}{0.2321}$, and therefore $m = \frac{\text{Log. } r - \text{Log. } 0.2321}{\text{Log. } s}$, and by substituting their corresponding values, instead of r and s we shall have the values of m or the numbers in the fourth column.

TABLE IV. *Containing the resistance of a Plane Surface moving in a Fluid, and placed at different angles to the path of its motion.*

Angle of inclination.	Resistance by experiment.	Resistance by theory.	Power of the sine of the angle to which the resistance is proportional.
Degrees.	Troy ounces.	Troy ounces.	Experiments.
10	0.0112	0.0012	1.73
20	0.0364	0.0093	1.73
30	0.0769	0.0290	1.54
40	0.1174	0.0616	1.54
50	0.1552	0.1043	1.51
60	0.1902	0.1476	1.38
70	0.2125	0.1926	1.42
80	0.2237	0.2217	2.41
90	0.2321	0.2321	
1	2	3	4

291. According to the theory the resistance should vary as the cube of the sine, whereas from an angle of 90° it decreases in a less ratio, but not as any constant power, nor as any function of the sine and cosine. Hence the actual resistance always exceeds that which is deduced from theory, assuming the perpendicular resistance to be the same. The cause of this difference is partly owing to our theory neglecting that part of the force which after resolution acts parallel to the plane, but which, according to experiments, is really a part of the force which acts upon the plane.

On the Resistance of Fluids.

Experiments with hemispheres, globes, and cylinders.

292. Mr Vince made also a number of experiments on the resistance of hemispheres, globes, and cylinders, which moved with a velocity of 0.542 feet per second. He found that the resistance to the spherical side of a hemisphere was to the resistance on its base as 0.034 is to 0.08339; that the resistance of the flat side of a hemisphere was to the resistance of a cylinder of the same diameter, and moving with the same velocity, as 0.08339 is to 0.07998; and that the resistance to a complete globe is to the resistance of a cylinder of the same diameter, and with the same velocity, as 1 : 2.23.

Determination of the resistance when the body is struck by the moving fluid.

293. The following results were obtained, when the plane was struck by the moving fluid. The second column of the following table contains the resistance by experiment, and the third column the resistance by theory from the perpendicular force, supposing it to vary as the sine of the inclination.

TABLE V. *Containing the Resistance of a Plane struck by the Fluid in Motion, and inclined at different angles to the direction of its path.*

Angle of inclination.	Resistance by experiment.			Resistance by theory.		
Degrees.	Oz.	dwts.	grs.	Oz.	dwts.	grs.
90	1	17	12	1	17	12
80	1	17	0	1	16	22
70	1	15	12	1	15	6
60	1	12	12	1	12	11
50	1	18	10	1	18	17
40	1	4	10	1	4	2
30	0	18	18	0	18	18
20	0	12	12	0	12	19
10	0	6	4	0	6	12
1	2			3		

294. It appears from the preceding results, that the resistance varies as the sine of the angle at which the fluid strikes the plane, the difference between theory and experiment being such as might be expected from the necessary inaccuracy of the experiments.

By comparing the preceding table with Table IV., it will be found that the resistance of a plane moving in a fluid is to the resistance of the same plane when struck by the fluid in motion as 5 to 6. In both these cases the actual effect on the plane must be the same, and therefore, the difference in the resistance can arise only from the action of the fluid behind the body in the former case.

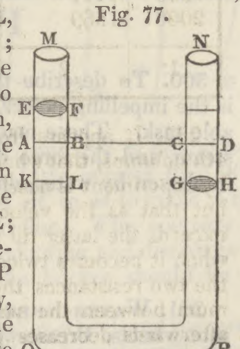
CHAPTER IV. ON THE OSCILLATION OF FLUIDS, AND THE UNDULATION OF WAVES.

PROP. I.

295. The oscillations of water in a syphon, consisting of two vertical branches and a horizontal one, are isochronous, and have the same duration as the oscillations of a pendulum, whose length is equal to half the length of the oscillating column of water.

Into the tube MNOP, having its internal diameter every where the same, introduce a quantity of water. When the water is in equilibrio, the two surfaces AB, CD will be in the same horizontal line AD. If this equilibrium be disturbed by making the syphon oscillate round the point y, the water will rise and fall alternately in the vertical branches after the syphon is at rest. Suppose the water to rise to EF in the branch MO, it will evidently fall to GH in the other branch, so that CG is equal to AE. Then it is evident, that the force which makes the water oscillate, is the weight of the column EFKL, which is double the column EABF; and that this force is to the whole weight of the water, as 2 AE is to AOPD. Now, let P be a pendulum, whose length is equal to half the length of the oscillating column AOPD, and which describes to the lowest point S arches PS, equal to AE; then 2 AE : AOPD = AE : QP, because AE is one-half of 2 AE, and QP one-half of AOPD. Consequently, since AOPD is a constant quantity, the force which makes the water oscillate is always proportional to the space which it runs through, and its oscillations are therefore isochronous. The force

Fig. 77.

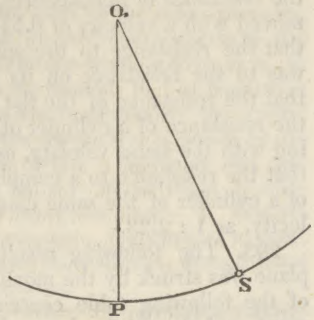


Oscillation of Fluids, &c.

Fig. 78.

which makes the pendulum describe the arch PS, is to the weight of the pendulum as PS is to PQ, or as AE is to PQ, since AE = PS ; but the force which makes the water oscillate, is to the weight of the whole water in the same ratio ; consequently, since the pendulum P, and the column AOPD, are influenced by the very same force, their oscillations must be performed in the same time. Q. E. D.

Fig. 78.



296. Cor. As the oscillations of water and of pendulums are regulated by the same laws, if the oscillating column of water is increased or diminished, the time in which the oscillations are performed will increase or diminish in the subduplicate ratio of the length of the pendulum.

Scholium.

297. This subject has been treated in a general manner, by Newton and different philosophers, who have shewn how to determine the time of an oscillation, whatever be the form of the syphon. See the *Principia*, lib. ii. Prop. 45, 46. Bossut's *Traité d'Hydrodynamique*, tom. 1. *Notes sur le Chap. II. Part II.* Bernoulli *Opera*, tom. iii. p. 125, and *Encyclopédie*, art. *Ondes*.

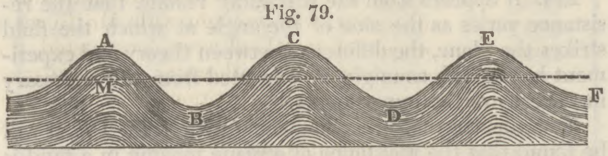
Prop. II.

On the undulation of waves.

298. The undulations of waves are performed in the same time as the oscillations of a pendulum whose length is equal to the breadth of a wave, or to the distance between two neighbouring cavities or eminences.

In the waves ABCDEF, the undulations are performed

Fig. 79.



in such a manner, that the highest parts ACE become the lowest ; and as the force which depresses the eminences ACE is always the weight of water contained in these eminences, it is obvious, that the undulations of waves are of the same kind as the undulations or oscillations of water in a syphon. It follows, therefore, from Prop. I. that if we take a pendulum, whose length is one-half BM, or half the distance between the highest and lowest parts of the wave, the highest parts of each wave will descend to the lowest parts during one oscillation of the pendulum, and in the time of another oscillation will again become the highest parts. The pendulum, therefore, will perform two oscillations in the time that each wave performs one undulation, that is, in the time that each wave describes the space AC or BD, between two neighbouring eminences or cavities, which is called *the breadth of the wave.* Now, if a pendulum, whose length is one-half BM, performs two oscillations in the above time, it will require a pendulum four times that length to perform only one oscillation in the same time, that is, a pendulum whose length is AC or BD, since $4 \times \frac{1}{2}$ BM = 2 BM = AC or BD. Q. E. D.

Scholium.

299. The explanation of the oscillation of waves contained in the two preceding propositions, was first given by Sir Isaac Newton, in his *Principia*, lib. ii. Prop. 44. He considered it only as an approximation to the truth, since it supposes the waves to rise and fall perpendicularly like the water in the vertical branches of the syphon, while their real motion is partly circular. The theory of Newton was, nevertheless, adopted by succeeding philosophers, and gave rise to many analogous discussions respecting the undulation of waves. Very lately, however, an attempt has been made by M. Flaugergues, to overturn the theory of Newton. From a number of experiments on the motion and figure of waves, an account of which may be seen in the *Journal des Sçavans*, for October 1789, M. Flaugergues concludes, that a wave is not the result of a motion in the particles of water, by which they ascend and descend alternately in a serpentine line, when moving from the place where the water received the shock ; but that it is an intumescence which this shock occasions around the place where it is received, by the depression that is there produced. This intumescence afterwards propagates itself circularly, while it removes from the place where the shock first raised it above the level of the stagnant water. A portion of the stagnant water then flows from all sides into the hollow formed at the place where the shock was received ; this hollow is thus heaped with fluid, and the water is elevated so as to produce all around another intumescence, or a new wave, which propagates itself circularly as before. The repetition of this effect produces on the surface of the water a number of concentric rings, successively elevated and depressed, which have the appearance of an undulatory motion. This interesting subject has also been discussed by M. La Grange, in his *Mécanique Analytique*, to which we must refer the reader for farther information. See History of Hydrodynamics, art. 21.

PART III.—ON HYDRAULIC MACHINERY.

Hydraulic machines.

300. To describe the various machines in which water is the impelling power, would be an endless and unprofitable task. Those machines which can be driven by wind, steam, and the force of men or horses, as well as they can be driven by water, do not properly belong to the science of hydraulics. By hydraulic machinery, therefore, we are to understand those various contrivances by which water can be employed as the impelling power of machinery ; and those machines which are employed to raise water, or which could not operate without the assistance of that fluid.

CHAPTER I. ON WATER-WHEELS.

Different kinds of water-wheels

301. Water-wheels are divided into three kinds, Overshot-wheels, Breast-wheels, and Undershot-wheels, which derive their names from the manner in which the water is delivered upon their circumferences.

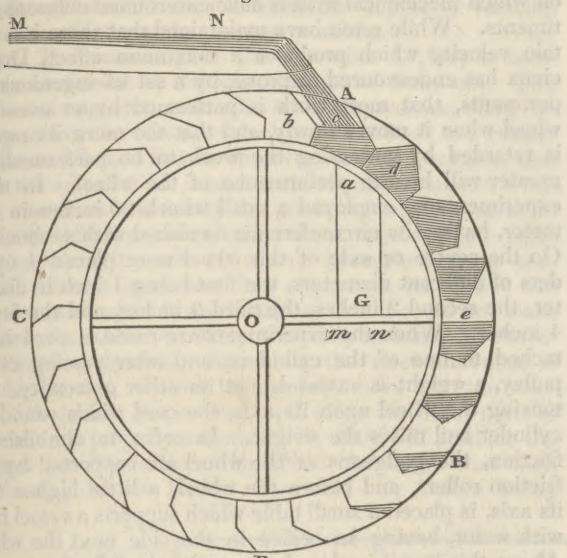
Sect. I. *On Overshot-Wheels.*

302. An overshot-wheel is a wheel driven by the weight of water, conveyed into buckets disposed on its circumfe-

On Water-Wheels.

rence. It is represented in fig. 80, where ABC is the circumference of the wheel furnished with a number of buck-

Fig. 80.



ets. The canal MN conveys the water into the second bucket from the top Aa. The equilibrium of the wheel is therefore destroyed; and the power of the bucket Aa, to turn the wheel round its centre of motion O, is the same as if the weight of the water in the bucket were suspended at m, the extremity of the lever Om, c being the centre of gravity of the bucket, and Om a perpendicular let fall from the fulcrum O to the direction cm, in which the force is exerted. In consequence of this destruction of equilibrium, the wheel will move round in the direction AB, the bucket Aa will be at d, and the empty bucket b will take the place of Aa, and receive water from the spout N. The force acting on the wheel is now the water in the bucket d acting with a lever nO, and the water in the bucket Aa acting with a lever mO. The velocity of the wheel will therefore increase with the number of loaded buckets, and with their distance from the vertex of the wheel; for the lever by which they tend to turn the wheel about its axis, increases as the buckets approach to c, where their power, represented by eO, is a maximum. After the buckets have passed e, the lever by which they act gradually diminishes, they lose by degrees a small portion of their water; and as soon as they reach B it is completely discharged. When the wheel begins to move, its velocity will increase rapidly till the quadrant of buckets be is completely filled. While these buckets are descending through the inferior quadrant eP, and the buckets on the left hand of b are receiving water from the spout, the velocity of the wheel will still increase; but the increments of velocity will be smaller and smaller, since the levers by which the inferior buckets act are gradually diminishing. As soon as the highest bucket Ac has reached the point B, where it is emptied, the whole semicircumference nearly of the wheel is loaded with water; and when the bucket at B is discharging its contents, the bucket at A is filling, so that the load in the buckets, by which the wheel is impelled, will be always the same, and the velocity of the wheel will become uniform.

Method of computing the momentum of water in the loaded arch.

303. In order to find the power of the loaded arch to turn the wheel, or, which is the same thing, to find a weight which, suspended at the opposite extremity C, will balance the loaded arch or keep it in equilibrio, we must multiply the weight of water in each bucket by the length of the virtual lever by which it acts, and take the sum of all these momenta for the momentum of the loaded arch. It will be much easier, however, and the result will be the same, if we multiply the weight of all the water on the arch AB, by the distance of its centre of gravity G, from the fulcrum or centre of motion O. Now, by the property of the centre of gravity (see MECHANICS), the distance of the centre of gravity of a circular arch from its centre, is a fourth proportional to half the arch, the radius, and the sine of half the arch. Since the vertical bucket b has no power to turn the wheel if it were filled, and since two or three buckets between B and P are always empty, we may safely suppose that the loaded arch never exceeds 160°, so that if R = radius of the wheel in feet, we shall have the length of half the loaded arch, or $80° = 2\,R \times 3.1416 \times \frac{80}{360} = R \times 1.396$; and the distance of the centre of gravity from the fulcrum O, $= GO = \frac{R \times \text{Sin. } 80°}{R \times 1.396}$. Now, if N be the number of buckets in the wheel, $\frac{160\,N}{360}$, or $\frac{4\,N}{9}$, will be the number of buckets in the loaded arch; and if G be the number of ale gallons contained in each bucket, the weight of the water in each bucket will be $1.02 \times G$, pounds avoirdupois. The weight of the water, therefore, in the loaded arch, will be $\frac{4\,N}{9} \times 102\ G$, and consequently the momentum of the loaded arch will be

$$= \frac{4\,N}{9} \times 10.2\,G \times \frac{R \times \text{Sin. } 80°}{R \times 1.396} = \frac{4\,N}{9} \times 10.2\,G \times 0.6338$$

$$= \frac{4\,N}{9} \times 6.465\ G \text{ pounds avoirdupois.}$$

Hence, we have the following rule: Multiply the constant number 6.465 by $\frac{4}{9}$ of the number of buckets in the wheel, and this product by the number of ale gallons in each bucket; and the result will be the effective weight, or momentum of the water in the loaded arch. For a description of the best form that can be given to the buckets, see the article *WATER-Works*. Dr Robison has there recommended a mode of constructing the buckets invented by Mr Burns, who divided each bucket into two by means of a partition; but the writer of this article is assured, on the authority of an ingenious mill-wright, who wrought with Mr Burns at the time when wheels of this kind were constructed, that the inner bucket is never filled with water, and that much of the power is thus lost. The partition prevents the introduction of the fluid, and the water is driven backwards by the escape of the included air.

304. In order to determine the best form of the buckets, we must consider that the power of the wheel would be a maximum, if the whole of its semi-circumference were loaded with water. This effect would be obtained if the buckets had the shape shewn in fig. 81., where ABC is the form of the bucket, AB being a continuation of the radius, and BC part of the circumference of the wheel, and nearly equal to AD. But as a small aperture at CE will neither admit nor discharge the water, the form shewn in fig. 82. has been proposed by Sir David Brewster as the best. In this construction, BC is made a little larger than BE, and AB is diminished so as to make the angle ABC a little greater than 90°. The angles AB should be rounded off, so as to make ABC a curve, as indicated by the dotted line. The aperture at dE must be sufficient for the introduction and discharge of the water, and the side BE of the bucket should be as smooth and even as possible.

Fig. 81.

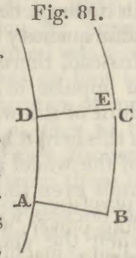


Fig. 82.

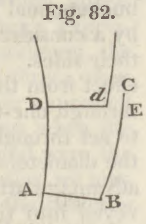
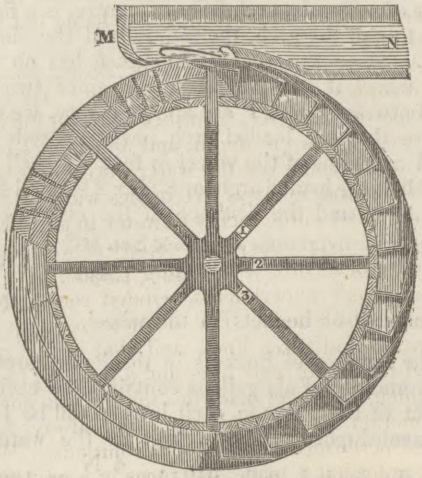


305. The construction of an overshot-wheel, and the mode of admitting the water into the buckets from the mill-course MN, is shewn in the following figure. In an overshot-

On Water-Wheels.

wheel constructed by Mr Smeaton, the wheel is exactly the height of the fall, and in another it exceeds that height, so as to be intermediate between an overshot and a breast wheel.

Fig. 83.



On the diameter of overshot-wheels relatively to the height of the fall.

306. In the construction of overshot-wheels, it is of great importance to determine what should be the diameter of the wheel relatively to the height of the fall. It is evident that its diameter cannot exceed the height of the fall. Some mechanical writers have demonstrated that, in theory, an overshot-wheel will produce a maximum effect when its diameter is two-thirds of that height, the water being supposed to fall into the buckets with the velocity of the wheel. But this rule is palpably erroneous, and directly repugnant to the results of experiment. For if the height of the fall be 48 feet, the diameter of the wheel will, according to this rule, be 32 feet; and the water having to fall through 16 feet before it reaches the buckets, will have a velocity of 32 feet per second, which, according to the hypothesis, must also be the velocity of the wheel's circumference. But Smeaton has proved, that a maximum effect is produced by an overshot-wheel of any diameter, when its velocity is only *three* feet per second. The Chevalier de Borda has shewn, that overshot-wheels will produce a maximum effect when their diameter is equal to the height of the fall; and this is completely confirmed by Mr Smeaton's experiments. From a great number of trials, Mr Smeaton has concluded, "that the higher the wheel is in proportion to the whole descent, the greater will be the effect." Nor is it difficult to assign the reason of this. The water which is conveyed into the buckets can produce very little effect by its impulse, even if its velocity be great; both on account of the obliquity with which it strikes the buckets, and in consequence of the loss of water occasioned by a considerable quantity of the fluid being dashed over their sides. Instead, therefore, of expecting an increase of effect from the impulse of the water occasioned by its fall through one-third of the whole height, we should allow it to act through this height by its gravity, and therefore make the diameter of the wheel as great as possible. But a disadvantage attends even this rule; for if the water is conveyed into the buckets without any velocity, which must be the case when the diameter of the wheel equals the height of the fall, the velocity of the wheel will be retarded by the impulse of the buckets against the water, and much power would be lost by the water dashing over them. In order, therefore, to avoid all inconveniences, the distance of the spout from the receiving bucket should, in general, be about two or three inches, that the water may be delivered with a velocity a little greater than that of the wheel; or, in other words, the diameter of an overshot-wheel should be two or three inches less than the greatest height of the fall; and yet it is no uncommon thing to see the diameters of these wheels scarcely one-half of that height. In such a construction the loss of power is prodigious.

On the proper velocity of overshot wheels. Experiments of Deparcieux on the velocity of overshot wheels.

307. The proper velocity of overshot-wheels is a subject on which mechanical writers have entertained different sentiments. While some have maintained that there is a certain velocity which produces a maximum effect, Deparcieux has endeavoured to prove, by a set of ingenious experiments, that most work is performed by an overshot-wheel when it moves slowly, and that the more its motion is retarded by increasing the work to be performed, the greater will be the performance of the wheel. In these experiments he employed a small wheel, 20 inches in diameter, having its circumference furnished with 48 buckets. On the centre or axle of this wheel were placed 4 cylinders of different diameters, the first being 1 inch in diameter, the second 2 inches, the third 3 inches, and the fourth 4 inches. When the experiments are made, a cord is attached to one of the cylinders, and after passing over a pulley, a weight is suspended at its other extremity. By moving the wheel upon its axis, the cord winds round the cylinder and raises the weight. In order to diminish the friction, the gudgeons of the wheel are supported by two friction rollers, and before the wheel, a little higher than its axis, is placed a small table which supports a vessel filled with water, having an orifice in the side next the wheel. Above this vessel is placed a large bottle full of water and inverted, having its mouth immersed a few lines in the water, so that it empties itself in proportion as the water in the vessel is discharged from the orifice. The quantity of water thus discharged is always the same, and is conveyed from the orifice by means of a canal to the buckets of the wheel. With this apparatus he obtained the following results.

Diameters of the Cylinders.	Altitude through which 12 ounces were elevated.		Altitude through which 24 ounces were elevated.	
Inches.	Inches.	Lines.	Inches.	Lines.
1	69	9	40	0
2	80	6	43	6
3	85	6	44	6
4	87	9	45	3

Result the preceding experiment.

308. When the large cylinders were used, the velocity of the wheel was smaller, because the resistances are proportional to their diameter, the weight being the same. Hence it appears, by comparing the four results in column 2d with one another, and also the four results in column 3d, that when the wheel turns more slowly, the effect, which is in this case measured by the elevation of the weight always increases. When the weight of 24 ounces was used, the resistance was twice as great, and the velocity twice as slow, as when the 12 ounce weight was employed. But by comparing the results in column 2d with the corresponding results in column 3d, it appears, that when the 24 ounce weight was employed, and the velocity was only one-half of what it was when the 12 ounce weight was used, the effect was *more than one-half*, the numbers in the 3d column being more than one-half the numbers in the 2d. Hence we may conclude, that the slower an overshot-wheel moves, the greater will be its performance.

An overshot-wheel does more work the slower it moves.

There is a velocity which gives a maximum effect.

309. These experiments of Deparcieux presented such unexpected results, as to induce other philosophers to examine them with care. The Chevalier D'Arcy, in particular, considered them attentively. He maintained that there was a determinate velocity when the effect of the wheel reached its maximum; and he has shewn, by comparing the experiments of Deparcieux with his own formulæ, that the overshot-wheel which Deparcieux employed never

On ater- W els.

moved with such a small velocity as corresponded with the maximum effect, and that if he had increased the diameter of his cylinders, or the magnitude of the weights, his own experiments would have exhibited the degree of velocity, when the effect was the greatest possible.

His pi- nio on- firm l by the peri- mei of Sm on;

310. The reasoning of the Chevalier D'Arcy is completely confirmed by the experiments of Smeaton. This celebrated engineer concludes with Deparcieux, that, *cæteris paribus*, the less the velocity of the wheel, the greater will be its effect. But he observes, on the contrary, that when the wheel of his model made about 30 turns in a minute, the effect was nearly the greatest; when it made 30 turns, the effect was diminished about one-twentieth part; and that when it made 40 it was diminished about one-fourth; when it made less than $18\frac{1}{4}$ turns, its motion was irregular, and when it was loaded so that it could not make 18 turns, the wheel was overpowered by its load. Mr Smeaton likewise observes, that when the circumferences of overshot-wheels, whether high or low, move with the velocity of three feet per second, and when the other parts of the work are properly adapted to it, they will produce the greatest possible effect. He allows, however, that high wheels may deviate farther from this rule before losing their power than low ones can be permitted to do; and assures us that he has seen a wheel 24 feet high moving at the rate of six feet per second, without losing any considerable part of its power, and likewise a wheel 33 feet high moving very steadily and well with a velocity but little exceeding two feet.

On Water-Wheels.

311. The experiments of the Abbé Bossut may also be adduced in support of the same reasoning. He employed a wheel 3 feet in diameter, furnished with 48 buckets, having each three inches of depth, and four inches of width. The canal which conveyed the water into the buckets was perfectly horizontal, and was five inches wide. It furnished uniformly 1194 cubic inches of water in a minute. The resistance to be overcome was a variety of weights fixed to the extremity of a cord, which, after passing over a pulley as in Deparcieux's experiments, winded round the cylindrical axle of the wheel. The diameter of this cylinder was two inches and seven lines, and that of the gudgeons or pivots of the wheel two lines and a half. The number of turns which the wheel made in a minute was not reckoned till its motion became uniform, which always happened when it had performed five or six revolutions. When the wheel was unloaded it made $40\frac{1}{4}$ turns in a minute.

And also by the experiments of Bossut.

Number of pounds raised.	Number of seconds in which the load was raised.	Number of revolutions performed by the wheel.	Effect of the wheel, or the product of the number of turns multiplied by the load.
11	60″	$11\frac{46}{48}$	$131\frac{32}{48}$
12	60	$11\frac{11}{48}$	$134\frac{36}{48}$
13	60	$10\frac{25}{48}$	$136\frac{37}{48}$
14	60	$9\frac{40}{48}$	$137\frac{32}{48}$
15	60	$9\frac{10}{48}$	$138\frac{6}{48}$
16	60	$8\frac{31}{48}$	$138\frac{16}{48}$
17	60	$8\frac{9}{48}$	$139\frac{9}{48}$
18	60	$7\frac{32}{48}$	138
19	The wheel turned but exceedingly slow.		
20	The wheel stopped though first put in motion by the hand to make it catch the water.		

312. It appears evidently from the last column, which we have computed on purpose, that the effect increases as the velocity diminishes; but that the effect is a maximum when the number of turns is $8\frac{9}{48}$ in a minute, being then $139\frac{9}{48}$. When the velocity was farther diminished by adding an additional pound to the resistance, the effect was diminished to 138, and when the velocity was still less, the wheel ceased to move.

Now since the wheel was three feet in diameter, and 9.42 feet in circumference, the velocity of its circumference will be about one foot four inches per second, when it performs $8\frac{9}{48}$ turns in a minute, or when the maximum effect is produced. With Mr Smeaton's model, the maximum effect was produced when the velocity of the wheel's circumference was two feet per second. So that the experiments both of Smeaton and Bossut concur to prove, that the power of overshot wheels increases as the velocity diminishes; but that there is a certain velocity, between one and two feet per second, when the wheel produces a maximum effect. Since when the wheel was unloaded it turned $40\frac{1}{4}$ times in a minute, and performed only $8\frac{9}{48}$ revolutions when its power was a maximum, the velocity of the wheel when unloaded will be to its velocity when the effect is the greatest, as five to one, nearly.

On the effect of overshot-wheels.

313. The Chevalier de Borda maintains that an overshot wheel will raise through the height of the fall a quantity of water equal to that by which it is driven, and Albert Euler has shewn that the effect of these wheels is very much inferior to the momentum or force which impels them. It appears, however, from Mr Smeaton's experiments, that when the work performed was a maximum, the ratio of the power to the effect was as four to three, when the height of the fall and the quantities of water expended were the least; but that it was as four to two when the heights of the fall and the quantities discharged were the greatest. By taking a mean between these ratios, we may conclude, in general, that in overshot-wheels the power is to the effect as three to one. In this case the power is supposed to be computed from the whole height of the fall; because the water must be raised to that height in order to be in a condition of producing the same effect a second time. When the power of the water is estimated only from the height of the wheel, the ratio of the power to the effect was more constant, being nearly as five to four.

Investigation of Albert Euler.

314. The theory of overshot-wheels has been ably discussed by Albert Euler and Lambert. The former of these philosophers has shewn that the altitude of the wheel should be made as great as possible; that the buckets should be made as capacious as other circumstances will permit; that their form should be such as to convey the

On Water-Wheels.

water as near the lowest point of the wheel as can be conveniently done; and that the motion of the wheel should be slow, that the buckets may be completely filled. He has likewise shewn that the effect of the wheel increases as its velocity is diminished; and that overshot-wheels should be used only when there is a sufficient height of fall. The results of Lambert's investigations are less consonant with the experiments of Smeaton. By examining the following table, which contains these results, it will appear at once that he makes the diameter of the wheel much smaller than it ought to be.

Table for Overshot-Mills.

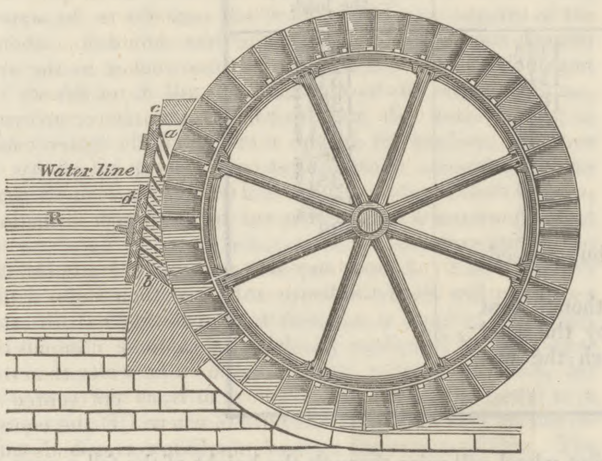
Sect. II. *On Breast-Wheels.*

Description of breast-wheels.

315. A breast-wheel partakes of the nature both of an overshot and an undershot wheel, and is driven partly by

Fig. 84.



the impulse, but chiefly by the weight, of the water. The mill-course (fig. 84), is made concentric with the wheel, which is fitted to it in such a manner that no water is allowed to escape at the sides and extremities of the floatboards. The water is delivered into the openings of the wheel through an iron grating ab, and its admission is regulated by two shutters c, d, the lowest of which is adjusted till a sufficient quantity of water passes over it; and the other shutter c is made to descend by machinery when the wheel is to be stopped, and the water retained in the reservoir R. According to Mr Smeaton, the effect of a wheel driven in this manner is equal "to the effect of an undershot-wheel whose head of water is equal to the difference of level between the surface of water in the reservoir, and the point where it strikes the wheel, added to that of an overshot whose height is equal to the difference of level between the point where it strikes the wheel and the level of the tail water."[1]

316. Mr Lambert, of the Academy of Sciences at Berlin, observes,[2] that a breast-wheel should be used when the fall of water is above four feet in height, and below ten. The following table is calculated from Lambert's formulæ, and exhibits at one view the results of his investigations.

Table for Breast-Mills.

Height of the fall in feet.	Breadth of the floatboards.	Depth of the floatboards.	Radius of the water-wheel reckoned from the extremity of the floatboards.	Velocity of the wheel per second.	Time in which the wheel performs one revolution.	Turns of the millstone for one of the wheel.	Force of the water upon the floatboards.	The length of $m\,n$, in fig. 84.	The length of $n\,o$, in fig. 84.	Water required per second to turn the wheel.

On Water-Wheels.

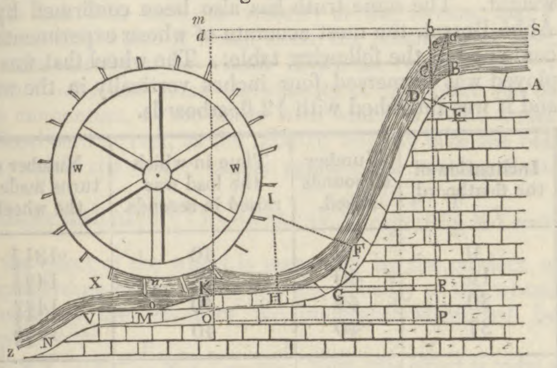
317. It appears from the preceding table, that when the altitude of the fall of water is below three feet, there is such an unsuitable proportion between the depth and width of the floatboards, that a breast wheel cannot well be employed. It is also evident, on the other hand, that when the height of the fall approaches to ten feet, the depth of the floatboards is too small in relation to their width. These two extremes, therefore, ought to be avoided in practice. The eleventh column of the table contains the quantity of water necessary to drive the wheel; but the total quantity of water should always exceed this, by the quantity, at least, that escapes between the mill-course and the sides and extremities of the floatboards.[1]

Sect. III. *On Undershot-Wheels.*

Description of an undershot wheel.

318. An undershot-wheel is a wheel with a number of floatboards disposed on its circumference, which receive the impulse of the water conveyed to the lowest point of the wheel by an inclined canal. It is represented in fig. 85, where WW is the water-wheel, and ABDFHKMV the

Fig. 85.



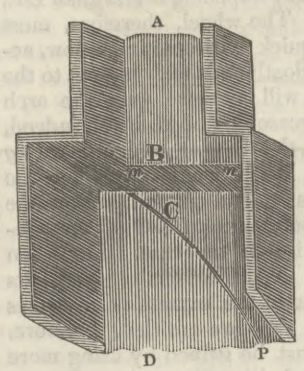
canal or mill-course, which conveys the water to K, where it strikes the plane floatboards *no*, &c. and makes the wheel revolve about its axis.

Construction of the mill-course.

319. In order to construct the mill-course to the greatest advantage, we must give but a very small declivity to the canal which conducts the water from the river. It will be sufficient to make AB slope about one inch in 200 yards, making the declivity, however, about half an inch for the first 48 yards, in order that the water may have sufficient velocity to prevent it from falling back into the river. The inclination of the fall, represented by the angle GCR, should be 25° 50′, or CR, the radius, should be to GR, the tangent of this angle, as 100 to 28, or as 25 to 12; and since the surface of the water S*b* is bent from *ab* into *ac* before it is precipitated down the fall, it will be necessary to incurvate the upper part BCD of the course into BD, that the water in the bottom may move parallel to the water at the surface of the stream. For this purpose take the points B, D about 12 inches distance from C, and raise the perpendiculars BE, DE. The point of intersection E will be the centre from which the arch BD is to be described; the radius being about $10\frac{1}{10}$ inches. Now, in order that the water may act more advantageously upon the floatboards of the wheel WW, it must assume a horizontal direction, with the same velocity which it would have acquired when it came to the point G. But, if the water were allowed to fall from C to G, it would dash upon the horizontal part HG, and thus lose a great part of its velocity. It will be necessary, therefore, to make it move along FH, an arch of a circle to which DF and KH are tangents in the points F and H. For this purpose make GF and GH each equal to three feet; and raise the perpendiculars HI, FI which will intersect one another in the point I, distant about four feet nine inches from the points F and H, and the centre of the arch FH will be determined. The distance HK, through which the water runs before it acts upon the wheel, should not be less than two or three feet, in order that the different filaments of the fluid may have attained a horizontal direction. If HK were too large, the stream would suffer a diminution of velocity by its friction on the bottom of the course. That no water may escape between the bottom of the course KH and the extremities of the floatboards, KL should be about three inches, and the extremity *o* of the floatboard *no* ought to reach below the line HKX, sufficient room being left between *o* and M for the play of the wheel; or KLM may be formed into the arch of a circle KM concentric with the wheel. The line LMV, which has been called the course of impulsion, should be prolonged so as to support the water as long as it can act upon the floatboards, and should be about nine inches distant from OP, a horizontal line passing through O the lowest point of the fall; for if OL were much less than nine inches, the water having spent the greatest part of its force in impelling the floatboard, would accumulate below the wheel, and retard its motion. For the same reason another course, which has been called the course ot discharge, should be connected with LMV by the curve VN, to preserve the remaining velocity of the water, which would otherwise be discharged by falling perpendicularly from V to N. The course of discharge, which is represented by the line VZ, sloping from the point O, should be about 16 yards long, having an inch of declivity for every two yards. The canal which reconducts the water from the course of discharge to the river should slope about four inches in the first 200 yards, three inches in the second 200 yards, decreasing gradually till it terminates in the river. But if the river to which the water is conveyed should, when swelled by the rains, force the water back upon the wheel, the canal must have a greater declivity to prevent this from taking place. Hence it is evident that very accurate levelling is requisite to the proper formation of the mill-course.

As it is of great importance that none of the water should escape, either below the floatboards or at their sides, without contributing to turn the wheel, the course of impulsion KV should be wider than the course at K, as represented in fig. 86, where CD the course of impulsion corresponds with LV in fig. 85, AB corresponds with HK, and BC with KL. The breadth of the floatboards, therefore, should be wider than *mn*, and their extremities should reach a little below B, like *no* in fig. 85. When these precautions are properly taken, no water can escape without exerting its force upon the floatboards.

Fig. 86.



On the number of floatboards in undershot-wheels.

320. It has been disputed among philosophers, whether the wheel should be furnished with a small or a great number of floatboards. M. Pitot has shewn, that when the floatboards have different degrees of obliquity, the force of impulsion upon the different surfaces will be reciprocally as their breadths: Thus in fig. 87, the force of impulsion upon *he* will be to the force upon DO, as DO to *he*.[2] Hence he concludes that the distance between the floatboards should be equal to one-half of the immersed arch, or that when one floatboard is at the bottom of the wheel, and perpendi-

[1] See *Appendix to Ferguson's Lectures*, vol. ii. p. 189, 2d edit.

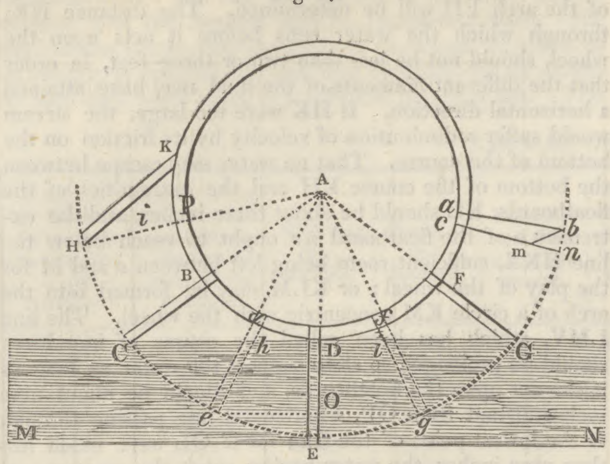
On Water-Wheels.

cular to the current, as DE, the preceding floatboard BC

Fig. 87.



should be just leaving the stream, and the succeeding one FG just immerging into it. For when the three floatboards FG, DE, BC have the same position as in the figure, the whole force of the current NM will act upon DE when it is in the most advantageous position for receiving it, whereas, if another floatboard *de* were inserted between FG and DE, the part *ig* would cover DO, and by thus substituting an oblique for a perpendicular surface, the effect would be diminished in the proportion of DO to *ig*. Hence it is evident, that, upon this principle, the depth of the floatboard DE should be always equal to the versed sine of the arch EG.[1]

Rule given by Pitot,

proved to be inaccurate.

321. Notwithstanding the plausibility of this reasoning, it will not be difficult to shew that it is destitute of foundation. It is evident from fig 87, that when one of the floatboards DE is perpendicular to the stream, it receives the whole impulse of the water in the most advantageous manner. But when it arrives at the position *de*, and the succeeding one FG at the position *fg*, so that the angle *e* A *g* may be bisected by the perpendicular AE, the situation of these floatboards will be the most disadvantageous, for a great part of the water will escape between the extremities *g* and *e* of the floatboards without striking them, and the part *ig* of the floatboards, which is really impelled, is less than DE, and oblique to the current. The wheel, therefore, must move irregularly, sometimes quick and sometimes slow, according to the position of the floatboards with respect to the stream; and this inequality will increase with the arch plunged in the water. The reasoning of M. Pitot, indeed, is founded on the supposition, that if another floatboard *fg* were placed between FG and DF, it would annihilate the force of the water that impels it, and prevent any of the fluid from striking the corresponding part DO of the preceding floatboard. But this is not the case. For when the water has acted upon *fg*, it still retains a part of its motion, and after bending round the extremity *g*, strikes DE with its remaining force. We are entitled, therefore, to conclude that advantage must be gained by using more floatboards than are recommended by Pitot.

The number of the floatboards should be as great as possible.

322. It is evident from the preceding remarks, that in order to remove any inequality of motion in the wheel, and prevent the water from escaping below the extremities of the floatboards, the wheel should be furnished with the greatest possible nnmber of floatboards, without loading it too much, or enfeebling the rim on which they are fixed. This rule was first given by M. Dupetit Vandin;[2] and it is easily perceived, that if the mill-wright should err in using too many floatboards, this error in excess will be perfectly trifling, and that a much greater loss of power would be occasioned by an error in defect.

On Wa- Whee-

Form of the floa- boards.

323. The section of the floatboards ought not to be rectangular, like *a b n c* in fig. 87, but should be bevelled like *a b m c*. For if they were rectangular, the extremity *b n* would interrupt a portion of the water which would otherwise fall on the corresponding part of the preceding floatboard. In order to find the angle *a b m*, subtract from 180 degrees the number of degrees contained in the immersed arch CEG, and the half of the remainder will be the angle required.

Positio- the floa- boards.

324. It has been maintained by M. Pitot and other philosophers, that the floatboards should be a continuation of the radius, or perpendicular to the rim, as in fig. 85. This, indeed, is true in theory, but it appears from the most unquestionable experiments, that they should be inclined to the radius. This important fact was discovered by Deparcieux in 1753, and proved by several experiments. When the floatboards are inclined, the water heaps up on their surface, and acts not only by its impulse, but also by its weight. The same truth has also been confirmed by the Abbé Bossut, the most accurate of whose experiments are contained in the following table. The wheel that was employed was immersed four inches vertically in the water, and it was furnished with 12 floatboards.

Inclination of the floatboard.	Number of pounds raised.	Time in which the load was raised in seconds.	Number of turns made by the wheel.
0	40	40	$13\frac{17}{48}$
15	40	40	$14\frac{21}{48}$
30	40	40	$14\frac{22}{48}$
37	40	40	$14\frac{15}{48}$
1	2	3	4

325. It is obvious, from the preceding table, that the wheel made the greatest number of turns, or moved with the greatest velocity, when the number of floatboards was between 15 and 30. When the water-wheels are placed on canals that have little declivity, and in which the water can escape freely after its impulse upon the floatboards, it would be proper to make the floatboards a continuation of the radius. But when they move in an inclined mill-course, an augmentation of velocity may be expected from an inclination of the floatboards.

On th- proper- locity under- wheel- when effect maxim-

326. Having thus pointed out the most scientific method of constructing the wheel, and delivering the water upon its floatboards, we have now to determine the velocity with which it should move. It is evident that the velocity of the wheel must be always less than that of the water which impels it, even when there is no work to be performed; for a part of the impelling power is necessarily spent in overcoming the inertia of the wheel, and the resistance of friction. It is likewise obvious, that when the wheel has little or no velocity, its performance will be very trifling. There is, consequently, a certain proportion between the velocity of the water and the wheel, when its effect is a maximum. By the reasoning which is employed in the section on undershot-wheels in the article WATER-WORKS, Parent and Pitot found, that a maximum effect was produced when the velocity of the wheel was one-third of the velocity of the water; and Desaguliers,[3] Maclaurin,[4] Lambert,[5] and Atwood,[6] have adopted their conclusions.

[1] A table containing the number of floatboards for wheels of different diameters, and founded on this principle, has been given in the *Appendix to Ferguson's Lectures*, vol. ii. p. 149, 2d edit.

[6] *Nouv. Mémoires de l'Acad. Berlin*, 1775, p. 63.

On Water-Wheels.

In the calculus from which this result was deduced, it was taken for granted that the momentum or force of water upon the wheel is in the duplicate ratio of the relative velocity, or as the square of the difference between the velocity of the water and that of the wheel. This supposition, indeed, is perfectly correct when the water impels a single floatboard; for as the number of particles which strike the floatboard in a given time, and also the momentum of these, are each as the relative velocity of the floatboards, the momentum must be as the square of the relative velocity, that is, $M \doteqdot R^2$, M being the momentum, and R the relative velocity. But we have seen, in some of the preceding paragraphs, that the water acts on more than one floatboard at a time. Now, the number of floatboards acted upon in a given time will be as the velocity of the wheel, or inversely as the relative velocity; for if you increase the relative velocity, the velocity of the water remaining the same, you must diminish the velocity of the wheel. Consequently, we shall have $M \doteqdot \frac{R^2}{R}$ or $M \doteqdot R$; that is, the momentum of the water acting upon the wheel is directly as the relative velocity.

327. Let V be now the velocity of the stream, and F the force with which it would strike the floatboard at rest, and v the velocity of the wheel. Then the relative velocity will be $V - v$; and since the velocity of the water will be to its momentum, or the force with which it would strike the floatboard at rest, as the relative velocity is to the real force which the water exerts against the moving floatboards, we shall have $V : V - v = F : F \times \frac{\overline{V-v}}{V} = \frac{F}{V} \times \overline{V-v}$. But the effect of the wheel is measured by the product of the momentum of the water and the velocity of the wheel, consequently the effect of the undershot-wheel will be $v \times \frac{F}{V} \times \overline{V-v} = \frac{F}{V} \times \overline{V v - v^2}$. Now, this effect is to be a maximum, and therefore its fluxion must be equal to 0, that is, v being the variable quantity, $V\dot{v} - 2v\dot{v} = 0$, or $2v\dot{v} = V\dot{v}$. Dividing by $\dot{v}$, we have $2v = V$, and $v = \frac{V}{2}$, that is, the velocity of the wheel will be *one-half* the velocity of the fluid when the effect is a maximum.

328. This result, which was first obtained by the Chevalier de Borda, has been amply confirmed by the experiments of Mr Smeaton. "The velocity of the stream," says he, "varies at the maximum between one-third and one-half that of the water; but in all the cases in which most work is performed in proportion to the water expended, and which approach the nearest to the circumstances of great works, when properly executed, the maximum lies much nearer *one-half* than *one-third*, one-half seeming to be the true maximum, if nothing were lost by the resistance of the air, the scattering of the water carried up by the wheel," &c.

329. A result, nearly similar to this, was deduced from the experiments of Bossut. He employed a wheel whose diameter was three feet. The number of floatboards was at one time 48, and at another 24, their width being five inches, and their depth six. The experiments with the wheel, when it had 48 floatboards, were made in an inclined canal, supplied from a reservoir by an orifice two inches deep, the velocity being 300 feet in 27 seconds. The experiments with the wheel, when it had 24 floatboards, were made in a canal, contained between two vertical walls, 12 or 13 feet distant. The depth of the water was about seven or eight inches, and its mean velocity about 2740 inches in 40 seconds. The floatboards of the wheel were immersed about four inches in the stream.

40	$35\frac{1}{2}$	$19\frac{15}{48}$	60	$11\frac{40}{48}$
40	36	$18\frac{28}{48}$	61	$11\frac{30}{48}$
40			62	$11\frac{19}{48}$
			63	$11\frac{7}{48}$
			64	$10\frac{41}{48}$
			65	$10\frac{25}{48}$
			66	$10\frac{5}{48}$

330. As the effect of the machine is measured by the product of the load raised, and the time employed, it will appear, by multiplying the second and third columns, that the effect was a maximum when the load was $34\frac{1}{2}$ pounds, the wheel performing $20\frac{21}{48}$ revolutions in 40 seconds. By comparing the velocity of the centre of impression computed from the diameter of the wheel, and the number of turns which it makes in 40 seconds, with the velocity of the current, it will be found, that the velocity of the wheel, when its effect is the greatest possible, is nearly two-fifths that of the stream. From the two last columns of the table, where the effect is a maximum when the load is 60 pounds, the same conclusion may be deduced.

Method of constructing a millwright's table.

331. The proper velocity of the wheel being thus established, we shall proceed to point out the method of constructing a millwright's table for undershot-wheels, taking it for granted that the velocity of the wheel should be one-half the velocity of the stream, and that water moves with the same velocity as falling bodies.

Fig. 87.

1. Find the perpendicular height of the fall of water above the bottom of the mill-course, and having diminished this number by one-half the depth of the water at K, call that the height of the fall.

2. Since bodies acquire a velocity of 32.174 feet, by falling through the height of 16.087 feet; and as the velocities of falling bodies are as the square roots of the heights through which they fall, the square root of 16.087 will be to the square root of the height of the fall as 32.174 to a fourth number, which will be the velocity of the water. Therefore the velocity of the water may be always found by multiplying 32.174 by the square root of the height of the fall, and dividing that product by the square root of 16.087. Or it may be found more easily by multiplying the height of the fall by the constant quantity $64.348 = 2 \times 32.174$, and extracting the square root of the product. This root, abstracting from the effects of friction, will be the velocity of the water required.

3. Take *one-half* the velocity of the water, and it will be the velocity which must be given to the floatboards, or the number of feet they must move through in a second, in order to produce a maximum effect.

4. Divide the circumference of the wheel by the velocity of its floatboards per second, and the quotient will be the number of seconds in which the wheel revolves.

5. Divide 60 by the number last found, and the quotient will be the number of turns made by the wheel in a minute.

—Or the number of revolutions performed by the wheel in a minute may be found, by multiplying the velocity of the floatboards by 60, and dividing the product by the circumference of the wheel.

6. Divide 90, the number of revolutions which a millstone, five feet diameter, should make in a minute, by the number of revolutions made by the wheel in a minute; and the quotient will be the number of turns which the millstone ought to make for one revolution of the wheel.

7. Then, as the number of revolutions of the wheel in a minute is to the number of revolutions of the millstone in a minute, so must the number of staves in the trundle be to the number of teeth in the wheel, in the nearest whole numbers that can be found.

8. Multiply the number of revolutions performed by the wheel in a minute, by the number of revolutions made by the millstone for one of the wheel, and the product will be the number of revolutions made by the millstone in a minute.

332. By these rules, the following table has been computed for a water-wheel fifteen feet in diameter, which is a good medium size, the millstone being seven feet in diameter, and revolving 90 times in a minute.

TABLE I. *A New Mill-Wright's Table, in which the Velocity of the Wheel is one-half the Velocity of the Stream, the effects of Friction not being considered.*

Height of the fall of water.	Velocity of the water per second, friction not being considered.	Velocity of the wheel per second, being one-half that of the water.	Revolutions of the wheel per minute, its diameter being 15 feet.	Revolutions of the millstone for one of the wheel.	Teeth in the wheel and staves in the trundle.		Revolutions of the millstone per minute by these staves and teeth.

333. The preceding table (*Appendix to Ferguson's Lectures*, vol. ii. p. 174) supposes, according to theory, that the velocity of the wheel, at the maximum effect, is one-half that of the stream, which is nearly the case in practice, when the quantities of water discharged by the stream are considerable. "When we consider, however," observes the editor of the work now quoted, "that after every precaution has been observed, a small quantity of water will escape between the mill-course and the extremities of the floatboards, and that the effect is diminished by the resistance of the air and the dispersion of water carried up by the wheel, the propriety of making the wheel move with three-sevenths the velocity of the water will appear. The Chevalier de Borda supposes it never to exceed three-eighths; and Mr Smeaton and the Abbé Bossut found two-fifths to be the proper medium.[1] With three-sevenths, therefore, as the best medium, which differs only $\frac{1}{35}$th from $\frac{2}{5}$ths, the numbers in the following table have been computed. In Table I. the water was supposed to move with the same velocity as falling bodies, but owing to its friction on the mill-course, &c. this is not exactly the case. We have therefore deduced the velocity of the water in column second from the following formula, $V = \sqrt{\frac{172}{3} \times Rb - \frac{Hh}{2}}$, Fig. 85

in which V is the velocity of the water, Rb the absolute height of the fall, and Hh the depth of the water at the bottom of the course. The formula is founded on the experiments of Bossut, from which it appears, that if a canal be inclined one-tenth part of its length, this additional declivity will restore that velocity to the water which was destroyed by friction."

TABLE II. *A New Mill-Wright's Table, in which the Velocity of the Wheel is three-sevenths of the Velocity of the Water, and the effects of Friction on the Velocity of the stream reduced to computation.*

Height of the fall of water.	Velocity of the water per second, friction being considered.	Velocity of the wheel per second, being 3-7ths that of the water.	Revolutions of the wheel per minute, its diameter being 15 feet.	Revolutions of mill-stone for one of the wheel.	Teeth in the wheel and staves in the trundle.		Revolutions of the millstone per minute by these staves and teeth.
Feet.	Feet. 100 parts of a foot.	Feet. 100 parts of a foot.	Revol. 100 parts of a revol.	Revol. 100 parts of a revol.	Teeth.	Staves.	Revol. 100 parts of a revol.

[1] The great hydraulic machine at Marly was found to produce a maximum effect, when its velocity was two-fifths of that of the stream.

O Vater- eels.

334. In order that the wheel may move with a velocity duly adjusted to that of the current, we would not advise the mechanic to trust to the second column of Table II. for the true velocity of the stream, or to any theoretical results, even when deduced from formulæ founded on experiments. Bossut, with great justice, remarks, that "it would not be exact in practice to compute the velocity of a current from its declivity. This velocity ought to be determined by immediate experiment in every particular case." Let the velocity of the water, therefore, where it strikes the wheel, be determined by the method in the following paragraph. With this velocity, as an argument, enter column second of either of these tables, according as the velocity of the wheel is to be one-half or three-sevenths that of the stream, and take out the other numbers from the table.

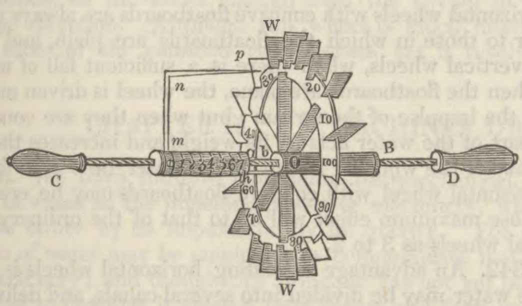
M aod of us g the ta .

D erent m aods of m suring th veloci- ty the st am.

335. Various methods have been proposed by different philosophers for measuring the velocity of running water; the method, by floating bodies, which Mariotte[1] employed, the bent tube of Pitot[2], the regulator of Guglielmini[3], the quadrant[4], the little wheel[5], and the method proposed by the Abbé Mann[6], have each their advantages and disadvantages. The little wheel was employed in the experiments of Bossut. It is the most convenient mode of determining the superficial velocity of the water; and, when constructed in the following manner, will be more accurate, it is hoped, than any instrument that has hitherto been used. The small wheel WW should be formed of the lightest materials. It should be about ten or twelve inches in diameter, and furnished with fourteen or sixteen floatboards. This wheel moves upon a delicate screw a B, passing through its axle B b; and when impelled by the

S ple in- st ment fc his p pose.

Fig. 83.



stream it will gradually approach towards D, each revolution of the wheel corresponding with a thread of the screw. The number of revolutions performed in a given time are determined upon the scale $m\ a$, by means of the index O h fixed at O, and moveable with the wheel, each division of the scale being equal to the breadth of a thread of the screw, and the extremity h of the index O h coinciding with the beginning of the scale, when the shoulder b of the wheel is screwed close to a. The parts of a revolution are indicated by the bent index $m\ n$, pointing to the periphery of the wheel, which is divided into 100 parts. When this instrument is to be used, take it by the handles CD, or when great accuracy is required, make it rest on the handles CD; and screw the shoulder b of the wheel close to a, so that the indices may both point to o the commencement of the scales. Then, by means of a stop-watch or pendulum, find how many revolutions of the wheel are performed in a given time. Multiply the mean circumference of the wheel (or the circumference deduced from the mean radius, which is equal to the distance of the centre of impulsion or impression from the axis b B) by the number of revolutions, and the product will be the number of feet through which the water moves in the given time. On account of the friction of the screw, the resistance of the air, and the weight of the wheel, its centre of impression will revolve with a little less velocity than that of the stream; but the diminution of velocity, arising from these causes, may be estimated with sufficient precision for all the purposes of the practical mechanic. (*Appendix to Ferguson's Lectures*, vol. ii. p. 177.)

On Water-Wheels.

Results of Smeaton's experiments.

336. It appears, from a comparison of the numerous and accurate experiments of Mr Smeaton, that, in undershot-wheels, the power employed to turn the wheel is to the effect produced as 3 to 1; and that the load which the wheel will carry at its maximum, is to the load which will totally stop it, as 3 to 4. The same experiments inform us, that the impulse of the water on the wheel, in the case of a maximum, is more than double of what is assigned by theory, that is, instead of four-sevenths of the column, it is nearly equal to the whole column. In order to account for this, Mr Smeaton observes, that the wheel was not, in this case, placed in an open river, where the natural current, after it had communicated its impulse to the float, has room on all sides to escape, as the theory supposes; but in a conduit or race, to which the float being adapted, the water could not otherwise escape than by moving along with the wheel. He likewise remarks, that when a wheel works in this manner, the water, as soon as it meets the float, receives a sudden check, and rises up against it like a wave against a fixed object; insomuch, that when the sheet of water is not a quarter of an inch thick before it meets the float, yet this sheet will act upon the whole surface of a float, whose height is three inches. Were the float, therefore, no higher than the thickness of the sheet of water, as the theory supposes, a great part of the force would be lost by the water dashing over it. In order to try what would be the effect of diminishing the number of floatboards, Mr Smeaton reduced the floatboards, which were originally 24 to 12. This change produced a diminution of the effect, as a greater quantity of water escaped between the floats and the floor. But when a circular sweep was adapted to the floor, and made of such a length that one float entered the curve before the preceding one quitted it, the effect came so near to the former, as to afford no hopes of increasing it by augmenting the number of floats beyond 24 in this particular wheel. Mr Smeaton likewise deduced, from his experiments, the following maxims.

1. That the virtual or effective head being the same, the effect will be nearly as the quantity of water expended.
2. That the expense of water being the same, the effect will be nearly as the height of the virtual or effective head.
3. That the quantity of water expended being the same, the effect is nearly as the square of the velocity.
4. The aperture being the same, the effect will be nearly as the cube of the velocity of the water.

Undershot-wheels with floatboards inclined to the plane of the wheel.

337. We have hitherto supposed the floatboards, though inclined to the radius, to be perpendicular to the plane of the wheel. Undershot-wheels, however, have sometimes been constructed with floatboards inclined to the plane of the wheel. A wheel of this kind is represented in fig 89. where AB is the wheel, and CDEFGH the oblique floatboards. The horizontal current MN is delivered on the floatboards, so as to strike them perpendicularly. On account of the size of the floatboards, every filament of the water contributes to turn the wheel; and therefore its effect will be greater than in undershot wheels of the common form. Albert Euler imagines that the effect will be twice as great, and observes, that in order to produce such an

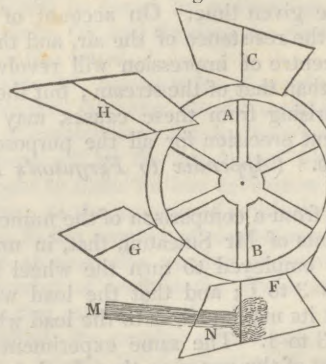
On Water-Wheels.

Fig. 89.



effect, the velocity of the centre of impression should be to the velocity of the water, as radius is to triple the sine of the angle by which the floatboards are inclined to the plane of the wheel. If this inclination, therefore, be 60°, the velocity of the wheel at the centre of impression ought to be to the velocity of the impelling fluid as 1 to $\frac{3\sqrt{3}}{2}$, that is, as 5 to 13 nearly, because Sin. $60° = \frac{\sqrt{3}}{2}$. When the inclination is 30°, the ratio of the velocities will be found to be as 2 to 3.

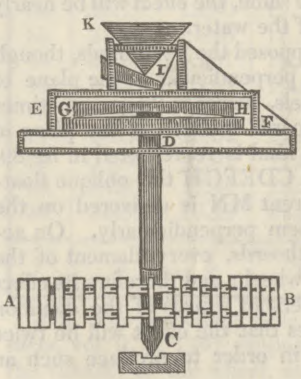
And also to the radius.

338. In wheels of this kind, the floats may also be advantageously inclined to the radius. In this case, the stream, which still strikes them perpendicularly, is inclined to the horizon. If the angle formed by the common section of the wheel and floatboards with the radius of the wheel, be $= m$; and if the angle by which the floatboards are inclined to the plane of the wheel be $= n$, then the angle which the floatboards should form with the direction in which the wheel moves, will be $= \overline{\text{Cos.}\, m \times \text{Sin.}\, n}$. In order, therefore, that the stream may strike the floatboards with a perpendicular impulse, its inclination to the horizon must be $= m$, and its inclination to the plane of the wheel $= 90° - n$. The less that the velocity of the water is, the greater should be the angle m; for there is, in this case, no danger that the celerity of the wheel be too great. The area of the floatboards ought to be much greater than the section of the current; and the interval between two adjacent floatboards should be so great, that before the one completely withdraws itself from the action of the water, the other should begin to receive its impulse.

On horizontal water-wheels.

339. Horizontal water-wheels have been much used on the Continent, and are strongly recommended to our notice by the simplicity of their construction. In fig. 90, AB is the large water-wheel which moves horizontally upon its arbor CD. This arbor passes through the immoveable millstone EF at D, and being fixed to the upper one GH, carries it once round for every revolution of the great wheel. The mill-course is constructed in the same manner for horizontal as for vertical wheels, with this difference only, that the part $m\,B\,n\,C$, fig. 85 of which KL in fig. 86 is a section, instead of being rectilineal like mn, must be circular like $m\,P$, and concentric with the rim of the wheel, sufficient room being left between it and the tips of the floatboards for the play of the wheel. In this construction, where the water moves

Fig. 90.



in a horizontal direction before it strikes the wheel, the floatboards should be inclined about 25° to the plane of the wheel, and the same number of degrees to the radius, so that the lowest and outermost sides of the floatboards may be farthest up the stream.

340. Instead of making the canal horizontal before it delivers the water on the floatboards, they are frequently inclined in such a manner as to receive the impulse perpendicularly, and in the direction of the declivity of the mill-course. When this construction is adopted, the maximum effect will be produced when the velocity of the floatboards is not less than $\frac{5.67\sqrt{H}}{2 \text{ Sin. } A}$, where H represents the height of the fall, and A the angle which the direction of the fall makes with a vertical line. But as the quantity $\frac{5.67\sqrt{H}}{2 \text{ Sin. } A}$ evidently increases as the sine of A decreases, it follows, that without lessening the effect of these wheels, we may diminish the angle A, and thus augment considerably the velocity of the floatboards, according to the nature of the machinery employed; whereas, in vertical wheels, there is only one determinate velocity which produces a maximum effect.

341. In the southern provinces of France, where horizontal wheels are generally employed, the floatboards are made of a curvilineal form, so as to be concave towards the stream. The Chevalier de Borda observes, that in theory a double effect is produced when the floatboards are concave; but that effect is diminished in practice, from the difficulty of making the fluid enter and leave the curve in a proper direction. Notwithstanding this difficulty, however, and other defects which might be pointed out, horizontal wheels with concave floatboards are always superior to those in which the floatboards are plain, and even to vertical wheels, when there is a sufficient fall of water. When the floatboards are plane, the wheel is driven merely by the impulse of the stream; but when they are concave, a part of the water acts by its weight and increases the velocity of the wheel. If the fall of water be 5 or 6 feet, a horizontal wheel with concave floatboards may be erected, whose maximum effect will be to that of the ordinary vertical wheels as 3 to 2.

342. An advantage attending horizontal wheels is, that the water may be divided into several canals, and delivered upon several floatboards at the same time. Each stream will heap up on its corresponding floatboard, and produce a greater effect than if the force of the water had been concentrated on a single floatboard. Horizontal wheels may be employed with greatest advantage when a small quantity of water falls through a considerable height.

343. It has been disputed among mechanical philosophers, whether overshot or undershot wheels produce the greatest effect. M. Belidor maintained that the former were inferior to the latter, while a contrary opinion was entertained by Desaguliers. It appears, however, from Mr Smeaton's experiments, that in overshot-wheels the power is to the effect nearly as 3 to 2 or as 5 to 4 in general, whereas in undershot-wheels it is only as 3 to 1. The effect of overshot-wheels, therefore, is nearly double that of undershot-wheels, other circumstances being the same. In comparing the relative effects of water-wheels, the Chevalier de Borda remarks that overshot wheels will raise through the height of the fall, a quantity of water equal to that by which they are driven; that undershot vertical wheels will produce only three-eighths of this effect; that horizontal wheels will produce a little less than one-half of it when the floatboards are plain, and a little more than one-half of it when the floatboards have a curvilineal form.

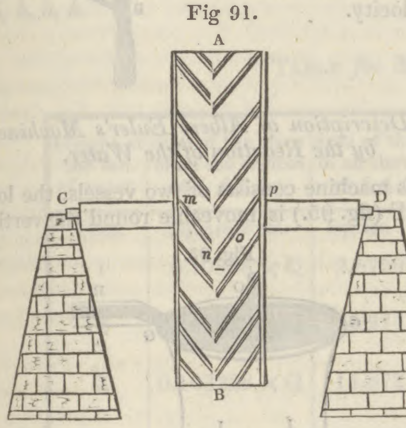
Besant's Undershot-Wheel.

344. The water-wheel invented by Mr Besant of Brompton is constructed in the form of a hollow drum, so as to resist the admission of the water. The floatboards are fixed obliquely in pairs on the periphery of the wheel, so that each pair may form an acute angle open at its vertex, while one of the floatboards extends beyond the vertex of the angle. A section of the water-wheel is represented in fig. 91, where AB is the wheel, CD its axis, and *mn op* the

Fig 91.



position of the floatboards. The motion of common undershot-wheels is greatly retarded by the resistance which the tail-water and the atmosphere oppose to the ascending floatboards; but in Besant's wheel this resistance is greatly diminished, as the floats emerge from the stream in an oblique direction. Although this wheel is much heavier than those of the common construction, yet it revolves more easily upon its axis, as the stream has a tendency to make it float.

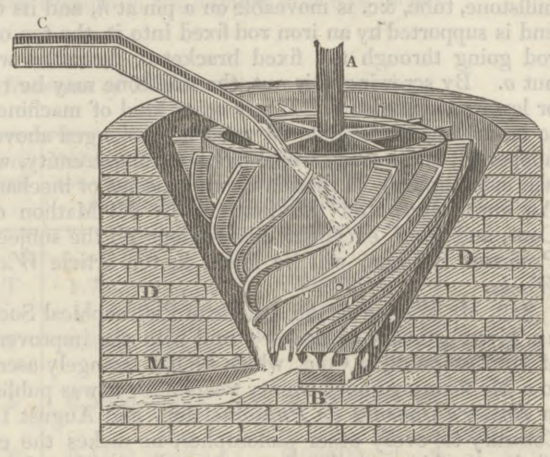
Machines driven by the Reaction of Water.

Conical Horizontal Wheel with Spiral Floatboards.

Description of a conical horizontal wheel with spiral floatboards.

345. In Guyenne and Languedoc, in the south of France, a kind of conical horizontal wheel is sometimes employed for turning machinery. It is constructed in the form of an inverted cone AB, fig. 92, with spiral floatboards winding

Fig. 92.



round its surface. The wheel moves on a vertical axis AB, in the building DD, and is driven chiefly by the impulse of the water conveyed by the canal C to the oblique floatboards, the direction of the current being perpendicular to the floatboards at the place of impact. When the impulsive force of the water is annihilated, it descends along the spirals, and continues to act by its weight till it reaches the bottom, when it is carried off by the canal M.

CHAPTER II. ON MACHINES DRIVEN BY THE REACTION OF WATER.

W er pro-
du s
gr er ef-
fec by its
re ion
th by its
im lse or
we ht.

346. We have hitherto considered the mechanical effects of water as the impelling power of machinery, when it acts either by its impulse or by its gravity. The reaction of water may be employed to communicate motion to machinery; and though this principle has not yet been adopted in practice, it appears from theory and from some detached experiments on a small scale, that a given quantity of water, falling through a given height, will produce greater effects by its reaction than by its impulse or its weight.

Sect. I. *On Dr Barker's Mill.*

D rip-
ti of Dr
B ker's
m

347. This machine, which is sometimes called Parent's mill, is represented in fig. 93, where MN is the canal that conveys the water into the upright tube TT, which communicates with the horizontal arm AB. The water will therefore descend through the upright tube into this arm, and will exert upon the inside of it a pressure proportioned to the height of the fall. But if two orifices A and B be perforated at the extremities of the arm, and on contrary sides, the pressure upon these orifices will be removed by the efflux of the water, and the unbalanced pressure upon the opposite sides of the arm will make the tube and the horizontal arm revolve upon the spindle D as an axis. This will be more easily understood, if we suppose the orifices to be shut up, and consider the pressure upon a circular inch of the arm opposite to the orifice, the orifice being of the same size. The pressure upon this circular inch will be equal to a cylinder of water whose base is one inch in diameter, and whose altitude is the height of the fall; and the same force is exerted upon the

Fig. 93.

shut-up orifice. These two pressures, therefore, being equal and opposite, the arm A will remain at rest. But as soon as you open the orifice, the water will issue with a velocity due to the height of the fall; the pressure upon the orifice will of consequence be removed; and as the pressure upon the circular inch opposite to the orifice still con-

Machines driven by the Reaction of Water.

tinues, the equilibrium will be destroyed, the arm will move in a retrograde direction.

348. The upright spindle D, on which the arm revolves, is fixed in the bottom of the arm, and screwed to it below by a nut. It is fixed to the upright tube by two cross bars, so as to move along with it. If a corn-mill is to be driven, the top of the spindle is fixed into the upper millstone *m*. The lower quiescent millstone *n* rests upon the floor K, in which is a hole, to let the meal pass into a trough below. The bridgetree GF, which supports the millstone, tube, &c. is moveable on a pin at *h*, and its other end is supported by an iron rod fixed into it, the top of the rod going through the fixed bracket 0, furnished with a nut *o*. By screwing this nut, the millstone may be raised or lowered at pleasure. If any other kind of machinery is to be driven, the spindle D must be prolonged above the hopper H, and a small wheel fixed to its extremity, which will communicate its motion to any species of mechanism. An improvement on this machine by M. Mathon de la Cour, and some excellent observations on the subject by Professor Robison, will be found in the article *Water-Works*.

349. Mr Waring of the American Philosophical Society, has given a theory of Barker's mill with the improvement of M. Mathon de la Cour, which he has strangely ascribed to a Mr Rumsey about twenty years after it was published in *Rozier's Journal de Physique*, Jan. and August 1775. Contrary to every other philosopher, he makes the effect of the machine equal only to that of a good undershot-wheel, moved with the same quantity of water, falling through the same height. The following rules, however, deduced from his calculus, may be of use to those who may wish to make experiments on the effect of this interesting machine.

Practical rules.

1. Make the arm of the rotatory tube or arm C, from the centre of motion to the centre of the aperture, of any convenient length, not less than one-third (one-ninth according to Mr Gregory,[1] who has corrected some of Waring's numbers) of the perpendicular height of the water's surface above their centres.

2. Multiply the length of the arm in feet by .614, and take the square root of the product for the proper time of a revolution in seconds, and adapt the other parts of the machinery to this velocity; or, if the time of a revolution be given, multiply the square of this time by 1.63 for the proportional length of the arm.

3. Multiply together the breadth, depth, and velocity per second, of the race, and divide the last product by 18.47 (times 14.27 according to Mr Gregory) the square root of the height, for the area of either aperture.

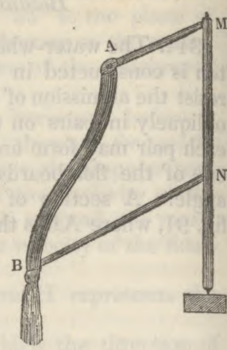
4. Multiply the area of either aperture by the height of the fall of water, and the product by $41\frac{5}{8}$ pounds (55.775 according to Mr Gregory), for the moving force estimated at the centres of the apertures in pounds avoirdupois.

5. The power and velocity at the aperture may be easily reduced to any part of the machinery by the simplest mechanical rules.

Form given to Barker's mill by Professor Segner.

350. Long after the preceding machine had been described in several of our English treatises on machines, Professor Segner published in his hydraulics, as an invention of his own, the account of a machine, differing from this only in form. MN was the axis of the machine, corresponding with DX in Barker's mill, and a number of tubes AB (fig. 94.) were also so arranged round this axis, that their higher extremities A formed a circular superficies, into which the water flowed from a reservoir. When the machine has this form, it has been shewn by Albert Euler that the maximum effect is produced when the velocity is infinite, and that the effect is equal to the power. As a considerable portion of the power, however, must be consumed in communicating to the fluid the circular motion of the tubes; and as the portion thus lost must increase with the velocity of the tube, the effect will in reality sustain a diminution from an increase of velocity.

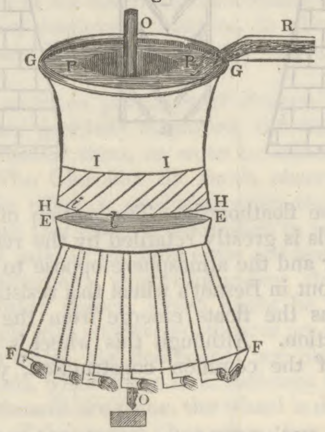
Fig. 94.



Sect. II. *Description of Albert Euler's Machine driven by the Reaction of the Water.*

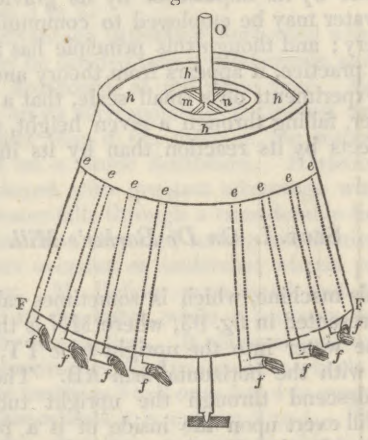
351. This machine consists of two vessels, the lowest of which EEFF (fig. 95.) is moveable round the vertical axis

Fig. 95.



OO, while the higher vessel remains immoveable. The form of the lowest vessel, which is represented by itself in fig. 96, is similar to that of a truncated bell, which is fastened by the cross beams *m*, *n* to the axis O, so as to move along with it. The annular cavity *hhhh* terminates at *ee* in several tubes *ef*, *ef*, *ef*, diverging from the axis. Through the lower extremities of these tubes, which are bent into a right angle, the water flowing from the cavity *hhhh* issues with a velocity due to the altitude of its surface in *h*, *h*, and produces by its reaction a rotatory and retrograde motion

Fig. 96.



[1] Gregory's *Mechanics*, vol. ii. p. 111.

round the axis OO. The cavity of the ring h, h, receives the water from the superior vessel GGHH, similar to the inferior vessel in fig. 95, but not connected with the axis OO. This vessel has also an annular cavity PP, into which the water is conveyed from a reservoir by the canal R. Around the lower part HH of the cavity, this vessel is divided into several apertures Ii, placed obliquely that the water may descend with proper obliquity into the inferior vessel. The width of the higher vessel at HH ought to be equal to the width of the lower vessel at EE, that the water which issues from the former may exactly fill the annular cavity h, h, h, h.

When the machine is constructed in this way, its maximum effect will be equal to the power, provided all its parts be proportioned and adjusted according to the results in the following table, computed from the formulæ of Albert Euler. In the table, Machines driven by the Reaction of Water.

Q = the quantity of water, or number of cubic feet of water furnished in a second.
T = the time, or number of seconds in which the lower vessel revolves.
B = the breadth of the annular orifice in inches.

TABLE *for Mills driven by the Reaction of Water.*

Table for mills driven by the reaction of water.

Height of the fall of water.	Sum of the areas of all the orifices at f, f, f, &c.	Sum of the areas of all the orifices at f, f, f, &c.	Mean radius of the annular orifice HH.	Difference between the altitude of the two vessels.	Tangent of the inclination of the tubes to the horizon.

1	2	3	4	5	6

The determinations in the preceding table are exhibited in a general manner, that the machine may be accommodated to local circumstances. The time of a revolution T, for instance, is left undetermined, because upon this time depends the magnitude of the machine; and T may be assumed of such a value that the dimensions of the machine may be suitable to the given place, or to the nature of the work to be performed.

352. In order to shew the application of the preceding table, let it be required to construct the machine when the height of the fall is five feet, and when the reservoir furnishes one cubic foot of water in a second. In this case Example.

On Machines for raising Water.

$Q = 1$, and therefore, by column 3, the sum of the areas of the orifices will be 11.52 square inches. Consequently, if there are twelve orifices, the area of each orifice will be $\frac{11.52}{12} = 0.96$ of a square inch. Suppose the time of a revolution to be $= 1$ second, or $T = 1$, then the 4th column will give the mean radius of the annular orifice $= 1.9894$ feet, or nearly two feet. Let the breadth of the annular orifice, or $B = \frac{1}{2}$ an inch, then the difference between the altitude of each vessel will be $0.3539 \times \frac{QQ}{TTBB} = 0.3539 \times \frac{1 \times 1}{\frac{1}{2} \times \frac{1}{2} \times 1 \times 1} = 0.3539 \times \frac{1}{\frac{1}{4}} = 0.3539 \times 4 =$ 1.4156 inches. Now, as the sum of the heights of the vessels must be always equal to the height of the fall, half that sum will in the present case be two feet six inches; and since half the difference of their altitudes is 7-10ths of an inch, the altitude of the superior vessel will be two feet six inches and seven-tenths, and that of the inferior vessel two feet five inches and three-tenths. It appears from the last column of the table, that the tangent of the inclination of the tubes is 0.1536, which corresponds with an angle of 8° 44′.

353. The theory of this machine has also been discussed by Leonhard Euler, in the *Mém. de l'Acad. Berlin*, vol. vi. p. 311; and its application to all kinds of work has been pointed out in a subsequent paper, entitled, *Application de la Machine Hydraulique de M. Segner à toutes forts d'ouvrage, et de ses avantages sur les autres Machines Hydrauliques dont on se sert ordinairement*, *Mém. Acad. Berlin*, tom. vii. 1752, p. 271. The results of Euler's analysis are not sufficiently practical for the use of the general reader. But it appears from his investigations, as well as from those of John Bernoulli and other philosophers, that the reaction of water is the most powerful way in which the force of that fluid can be employed.

354. It has often occurred to the writer of this article, that a very powerful hydraulic machine might be constructed by combining the impulse with the reaction of water. If the spout *a*, for example, instead of delivering the water into the higher vessel, were to throw it upon a number of curvilineal floatboards fixed on its circumference, and so formed as to convey the water easily into the spiral canals, we should have a machine something like the conical horizontal wheel in fig. 92, with spiral channels instead of spiral floatboards, and which would in some measure be moved both by the impulse, weight, and reaction of the water.

CHAPTER III. ON MACHINES FOR RAISING WATER.

Sect. I. *On Pumps.*

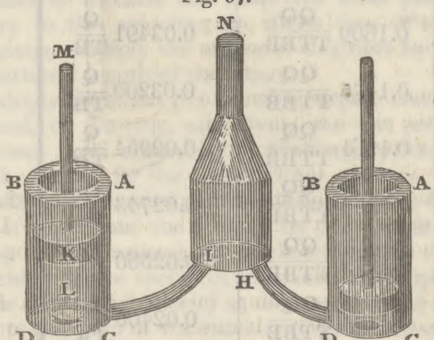
Reference to the article Pump.

355. The subject of pumps has been fully and ably discussed by Dr Robison under the article Pump, to which we must refer the reader for a complete view of the theory of the machine. In that article, however, a reference is made to the present for a description of the ancient pump of Ctesibius, and of those in common use to which it has given rise. To these subjects, therefore, we must now confine our attention.

Description of the original pump of Ctesibius.

356. The pump was invented by Ctesibius, a mathematician of Alexandria, who flourished under Ptolemy Psychon, about 120 years before Christ. In its original state, it is represented in fig. 97, where ABCD is a brass cylin-

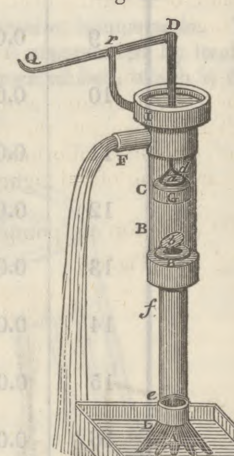
Fig. 97.



der with a valve L in its bottom. It is furnished with a piston MK made of green wood, so as not to swell in water, and adjusted to the bore of the cylinder by the interposition of a ring of leather. The tube CI connects the cylinder ABCD with another tube NH, the bottom of which is furnished with a valve I opening upwards. Now, when the extremity DC of the cylinder is immersed in water, and the piston MK elevated, the pressure of the water upon the valve L from below will be proportioned to the depth below the surface (41). The valve will therefore open, and admit the water into the cylinder. But when the piston is depressed, it will force the water into the tube CH, and through the valve I into the tube NH. As soon as the portion of water that was admitted into the cylinder ABCD, is thus impelled into the tube NH, the valve I will close. A second elevation of the piston will admit another quantity of fluid into the cylinder, and a second depression will force it into the tube NH; so that, by continuing the motion of the piston, the water may be elevated to any altitude in the tube. From this pump of Ctesibius are derived the three kinds of pumps now commonly used, the sucking, the forcing, and the lifting pump.

357. The common sucking pump is represented in fig. 98, where ICBL is the body of the pump immersed in the water at A. The moveable piston DG is composed of the piston rod D *d*, the piston or bucket G, and the valve *a*. The bucket H, which is fixed to the body of the pump, is likewise furnished with a valve *b*, which, like the valve *a*, should by its own weight lie close upon the hole in the bucket till the working of the engine commences. The valves are made of brass, and have their lower surface covered with leather, in order to fit the holes in the bucket more exactly. The moveable bucket G is covered with leather, so as to suit exactly the bore of the cylinder, and to prevent any air escaping between it and the pump. The piston DG may be elevated or depressed by the lever DQ, whose fulcrum is *r*, the extremity of the bent arm R *r*.

Fig. 98.



358. Let us now suppose the piston G to be depressed so that its inferior surface may rest upon the valve *b*. Then, if the piston G be raised to C, there would have been a vacuum between H and G if the valve *b* were immoveable. But as the valve *b* is moveable, and as the pressure of the air is removed from its superior surface, the air in the tube HL will, by its elasticity, force open the valve *b*, and expand itself through the whole cavity LC. This air, however, will be much rarer than that of the atmosphere; and since the equilibrium between the external

O Ma- chi s for r ing W er.

air and that in the tube LH is destroyed by the rarefaction of the latter, the pressure of the atmosphere on the surface of the water in the vessel K will predominate, and raise the water to about *e* in the suction pipe HL, so that the air formerly included in the space LC will be condensed to the same state as that of the atmosphere. The elasticity of the air both above and below the valve *b* being now equal, that valve will fall by its own weight. Let the piston DG be now depressed to *b;* the air would evidently resist its descent, did not the valve *a* open and give a free exit to the air in the space CH, for it cannot escape through the inferior valve *b*. When the piston reaches *b*, the valve *a* will fall by its weight; and when the piston is again elevated, the incumbent air will press the valve *a* firmly upon its orifice. During the second ascent of the piston to C, the valve *b* will rise, the air between *e* H will rush into HC; and in consequence of its rarefaction, and inability to counteract the pressure of the atmosphere, the water will rise to *f*. In the same way it may be shewn, that at the next stroke of the piston the water will rise through the box H to B, and then the valve *b* which was raised by it will fall when the bucket G is at C. Upon depressing the bucket G again, the water cannot be driven through the valve *b*, which is pressed to its orifice by the water above it. At the next ascent of the piston a new quantity of water will rise through H, and follow the piston to C. When the piston again descends, the valve *a* will open; and as the water between C and H cannot be pushed through the valve *b*, it will rise through *a*, and have its surface at C when the piston G is at *b*; but when the piston rises, the valve *a* being shut by the water above it, this water will be raised up towards I, and issue at the pipe F. A new quantity of water will rush through H, and fill the space HC: consequently, the surface of the fluid will always remain at C, and every succeeding elevation of the piston from *b* to C will make the column of water CH run out at the pipe F.

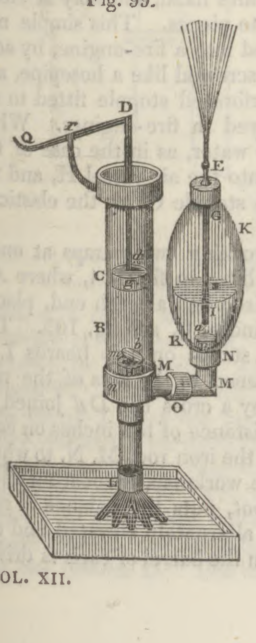
Th uck- ng ump wil ot rai water hig than 33 t.

359. As the water rises in the pipe CL solely by the pressure of the atmosphere; and as a column of water, 33 feet high, is equal in weight to a column of air of the same base, reaching from the earth's surface to the top of the atmosphere, the water in the vessel K will not follow the piston G to a greater altitude than 33 feet; for when it reaches this height, the column of water completely balances, or is in equilibrium with, the atmosphere, and therefore cannot be raised higher by the pressure of the external air.

De ip- ion f the for g- pu

360. The forcing-pump is represented in fig. 99, where D *d* is the piston attached to a solid plunger *g*, adjusted to the bore of the pipe BC by the interposition of a ring of leather. The rectangular pipe MMN communicates with the tube BC by the cavity round H; and its upper extremity P is furnished with a valve *a* opening upwards. An air-vessel KK is fastened to P, and the tube EGI is introduced into it so as to reach as near as possible to the valve *a*.

Fig. 99.



Mo of its ope ion.

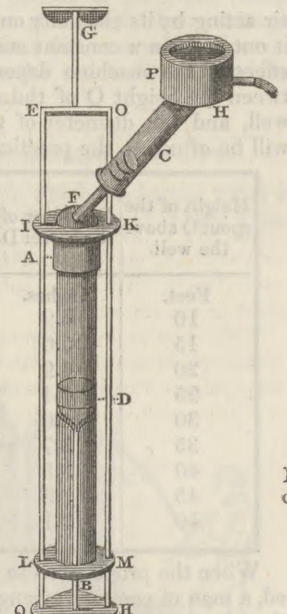
Let us now suppose the plunger D *g* to be depressed to *b*. As soon as it is elevated to C, the air below it will be rarefied, and the water will ascend through the valve *b* in the same way as in the sucking-pump, till the pipe is filled to C. The valve *b* will now be shut by the weight of the incumbent water; and therefore, when the plunger D *g* is depressed, it will force the water between C and *b* through the rectangular pipe MMN, into the air vessel KK. Before the water enters the air-vessel, it opens the valve *a*, which shuts as soon as the plunger is again raised, because the pressure of the water upon its under side is removed. In this way the water is driven into the air-vessel by repeated strokes of the plunger, till its surface is above the lower extremity of the pipe IG. Now, as the air in the vessel KK has no communication with the external air when the water is above I, it must be condensed more and more, as new quantities of water are injected. It will therefore endeavour to expand itself, and by pressing upon the surface H of the water in the air-vessel, it will drive the water through the tube IG, and make it issue at E in a continued stream, even when the plunger is rising to C. If the pipe GHI were joined to the pipe MMN at P, without the intervention of an air vessel, the stream of water would issue at F only when the plunger was depressed.

On Machines for raising Water.

Description of the lifting pump.

361. The lifting pump, which is only a particular modification of the forcing pump, is represented in fig. 100. The barrel AB is fixed in the immoveable frame KILM, the lower part of which is immersed in the water to be raised. The frame GEQHO consists of two strong iron rods EQ, OH, which move through holes in IK and LM, the upper and lower ends of the pump. To the bottom QH of this frame is fixed an inverted piston, with its bucket and valve uppermost at D. An inclined branch FH, either fixed to the top of the barrel, or moveable by a ball and socket, as represented at F, must be fitted to the barrel so exactly, as to resist the admission both of air and water. The branch FH is furnished with a valve C opening upwards. Let the pump be now plunged in the water to the depth of D. Then if the piston frame be thrust down into the fluid, the piston will descend, and the water by its upward pressure will open the valve at D, and gain admission above the piston. When the piston frame is elevated, it will raise the water above D along with it, and, forcing it through the valve, it will be carried off by the spout above H.

Fig. 100.



Mode of its operation.

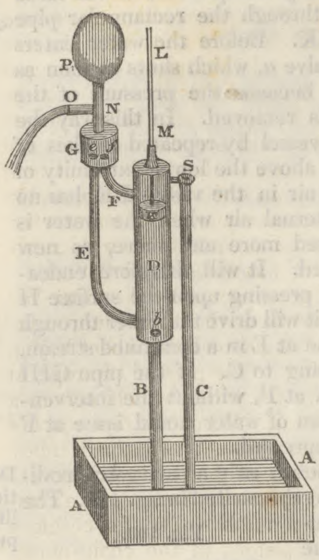
De la Hire's pump.

362. An ingenious pump, invented by De la Hire, is represented in fig. 101. It raises water equally quick by the descent as by the ascent of the piston. The pipes B, C, E, F, all communicate with the barrel MD, and have each a valve at their top, viz. at *b*, S, *e*, *f*. The piston rod LM and plunger K never rise higher than K, nor descend lower than D, KD being the length of the stroke. When the plunger K is raised from D to K, the pressure of the atmosphere forces the water through the valve *b*, and fills the barrel up to the plunger, in the very same way as in the forcing pump. When the plunger K is depressed to D, it forces the water between K and *b* up the pipe E, and through the valve *e* into the box G, where it issues at the spout O. During the descent of the plunger K, the valve *f* falls, and covers the top of the pipe F; and as the piston rod LM moves in a collar of leather at M, and is air-tight, the air above the plunger, between K and M, will be rare-

On Machines for raising Water.

fied, and likewise the air in the pipe CS, which communicates with the rarefied air by the valve S. The pressure of the air, therefore, will raise the water in CS, force it through the valve S, and fill the space above the plunger, expelling the rarefied air through the valve *f*. When the piston is raised from D to K, it will force the water through the bent pipe F into the box G, so that the same quantity of water will be discharged at O through the pipe F, during the ascent of the piston, as was discharged through the pipe E during the piston's descent. Above the pipe O is a close air-vessel P, so that when the water is driven above the spout O, it compresses the air in the vessel P, and this air acting by its elasticity on the surface of the water, forces it out at O in a constant and nearly equal stream. As the effect of the machine depends on a proper proportion between the height O of the spout above the surface of the well, and the diameter of the barrel, the following table will be of use to the practical mechanic.

Fig. 101.



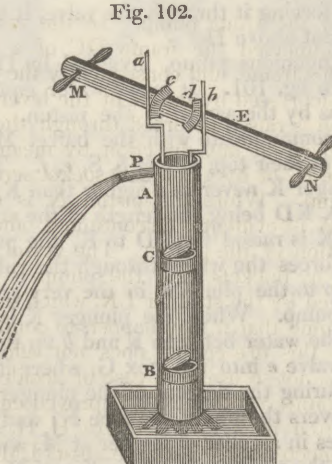
Height of the spout O above the well.	Diameter of the barrel D.	Height of the spout O above the well.	Diameter of the barrel D.
Feet.	Inches.	Feet.	Inches.
10	6.9	60	2.8
15	5.6	65	2.7
20	4.9	70	2.6
25	4.4	75	2.5
30	4.0	80	2.5
35	3.7	85	2.4
40	3.5	90	2.3
45	3.3	95	2.2
50	3.1	100	2.1

When the proportions in the preceding table are observed, a man of common strength will raise water much higher than he could do with a pump of the common construction.

Noble's pump.

363. A very simple pump, which furnishes a continued stream, is represented in fig. 102. It was invented by a Mr

Fig. 102.



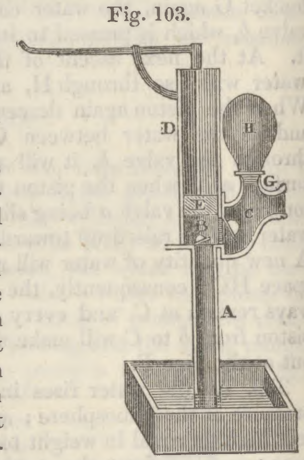
Noble, and consists of a working barrel AB, with two pistons C and B, which are moved up and down alternately by the rods fixed to the lever MN. The rod of the piston B passes through the piston C, and the piston C moves upon the rod AB. When the piston rod B is depressed and elevated, it will make the water rise in the barrel A, in the same way as in the sucking pump, whether the valve C be moveable or not. Let us now suppose that the water is raised to A. Then if the piston B is elevated by depressing the extremity N of the lever, the water at A will be raised higher in the barrel, and issue at the spout P; and when the same piston B is depressed by elevating the end N of the lever, the piston C is evidently raised, and the water above it will be expelled at P. This pump, therefore, will give a continued stream, for as the pistons ascend and descend alternately, one of them must always be forcing the water out at P. The pistons are elevated and depressed by means of toothed arches, *c* and *d*, working in the teeth of a rack, at the extremities *a*, *b* of the piston rod.

On Machines for raising Water.

Buchanan's pump.

364. The pump invented by Mr Buchanan is shewn in fig. 103. In the vertical section DGA, A is the suction barrel, D the working barrel, E the piston, G the spout, B the inner valve, and C the outer valve. These valves are of the kind called clack valves, and have their hinges generally of metal. It is easily seen that when the piston E is raised, the water will rise through the suction barrel A into the working barrel D, in the same way as in the sucking pump; and that when the piston E is depressed, it will force the water between it and the valve B, through the valve C, and make it issue at G. The points of difference between this pump and those of the common form, are,—that it discharges the water below the piston, and has its valves lying near each other. Hence the sand or mud which may be in the water, is discharged without injuring the barrel or the piston leathers; and as the valves B, C, may be of any size, they will transmit, without being choked, any rubbish which may rise in the suction barrels. If any obstruction should happen to the valves, they are within the reach of the workman's hand, and may be cleared without taking the pump to pieces. This simple machine may be quickly converted into a fire-engine, by adding the air-vessel H, which is screwed like a hosepipe, and by fixing in the spout G, a perforated stopple fitted to receive such pipes as are employed in fire-engines. When these additions are made, the water, as in the case of the forcing pump, will be driven into the air vessel H, and repelled through the perforated stopple G, by the elasticity of the included air.

Fig. 103.

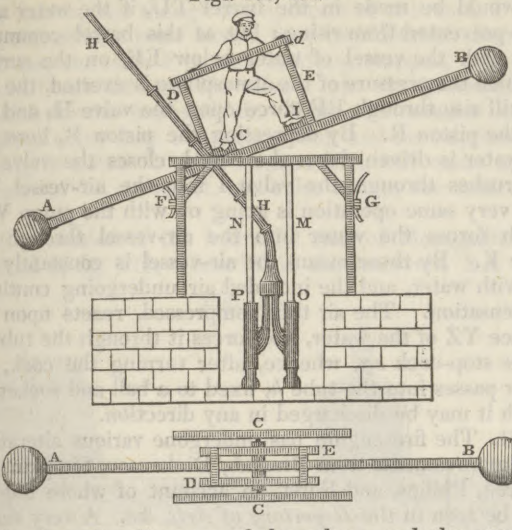


Balance pump.

365. A simple method of working two pumps at once, by means of a balance, is exhibited in fig. 104, where AB is the balance, having a large iron ball at each end, placed in equilibrium on the two spindles C, see fig. 105. The person who works the pump stands on two boards I, I, nailed to two cross pieces fastened to the axis of the machine, and supports himself by a cross bar D*d* joined to the two parts D, E. At the distance of ten inches on each side of the axis are suspended the iron rods M, N, to which the pistons are attached. The workman, by bearing alternately on the right and left foot, puts the balance in motion. The pistons M, N, are alternately elevated and depressed, and the water raised in the barrel of each is driven

into the pipe HH, in which it is elevated to a height pro-

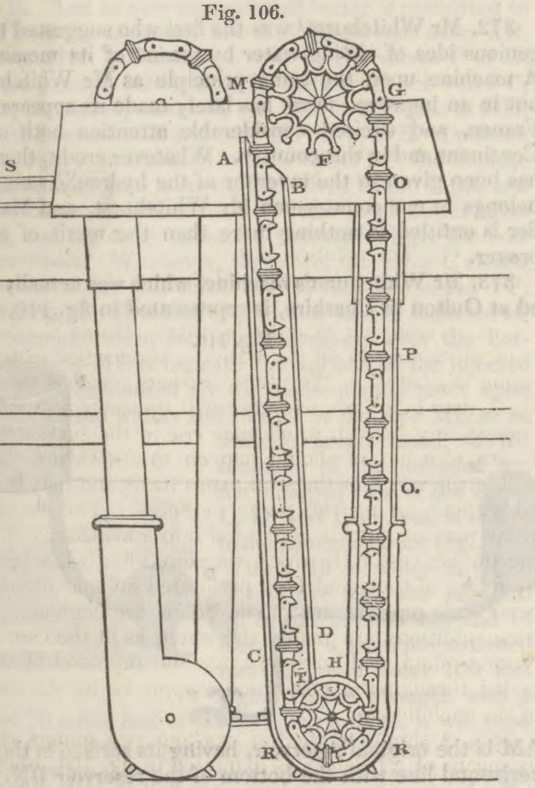
Figs. 104, 105.



portional to the diameter of the valves, and the power of the balance. In order to make the oscillations of the balance equal, and prevent it from acquiring too great a velocity, iron springs F, G, are fixed to the upright posts, which limit the length of its oscillations.

366. The chain pump is represented in fig. 106. It con-

Fig. 106.



sists of a chain MTHG, about 30 feet long, carrying a number of flat pistons M, N, O, P, Q, which are made to revolve in the barrels ABCD and GH, by driving the wheel F. When the flat pistons are at the lower part of the barrel T, they are immersed in the water RR, and as they rise in the barrel GH, they bring up the water along with them into the reservoir MG, from which it is conveyed by the spout S. The teeth of the wheel F are so contrived as to receive one-half of the flat pistons, and let them fold in; and sometimes another wheel like F is fixed at the bottom D. The distance of the pistons from the side of the barrel is about half an inch; but as the machine is generally worked with great velocity, the ascending pistons bring along with them into the reservoir as much water as fills the cavity GH. Sometimes chain pumps are constructed without the barrels ABCD and GH. In this case, the flat pistons are converted into buckets connected with a chain, which dip in the water with their mouths downwards, and convey it to the reservoir. The buckets are moved by hexagonal axles, and the distance between each is nearly equal to the depth of the buckets. Chain pumps are frequently placed in an inclined position, and in this position they raise the greatest quantity of water when the distance of the flat pistons is equal to their breadth, and when the inclination of the barrels is about 24° 21′.

On Machines for raising Water.

367. The hair-rope machine, invented by the Sieur Vera, operates on the same principle as the chain-pump. Instead of a chain of pistons moving round the wheel F (fig. 106.), a hair-rope is substituted. The part of the rope at T that is lowest always dips in the water, which, adhering to the rope, is raised along with it. When the rope reaches the top at G and M, it passes through two small tubes, which, being fixed in the bottom of the reservoir, prevent the water from returning into the well. Sometimes a common rope is employed, having a number of stuffed cushions fixed to it instead of the flat pistons in the chain-pump. These cushions carry the water along with them through the barrel HG, and deliver it into the reservoir.—For the description of other pumps, see the article Pump; and for pump mills, see the article Mill.

Hair-rope machine of the Sieur Vera.

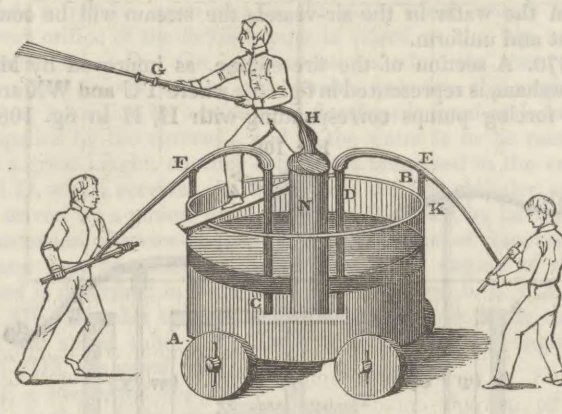
Machine with cushions instead of flat pistons.

Sect. II. *On Engines for Extinguishing Fire.*

368. The common fire-engine which discharges water in successive jets is represented in fig. 107, and is only a mo-

Common squirting engine.

Fig. 107.



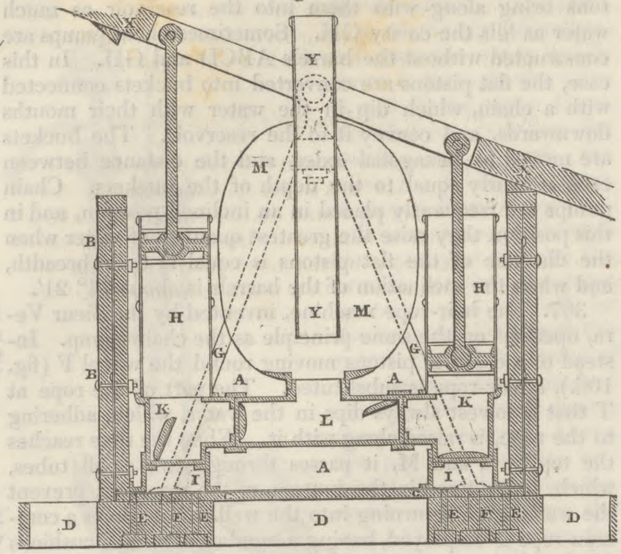
dification of the lifting pump. In the vessel AB, full of water, is immersed the frame DC of a common lifting pump. This frame, and consequently the piston N, is elevated and depressed by means of the levers E, F, and the water which is raised is forced through the pipe G, which may be moved in any direction by means of the elastic leather pipe H, or by a ball and socket screwed on the top of the pump. While the piston N is descending, the stream at G is evidently discontinued, and issues only at each elevation of the piston. The vessel AB is supplied with water by buckets, and the pump is prevented from being choked by the strainer LK, which separates from the water any mud that it may happen to contain.

369. As this fire-engine does not afford a continued stream, it is not so useful in case of accidents as when the stream is uninterrupted. An improved engine of this sort is represented in fig. 108, where H, H, are two forcing pumps connected with the large vessel LMM, and wrought by the levers X, X, moving upon Y as a fulcrum. This

Improved fire-engine.

apparatus is plunged and fastened in a vessel I I partly

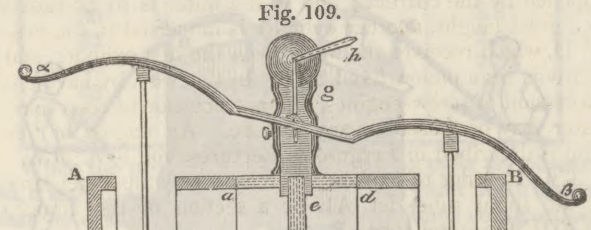
Fig. 108.



filled with water, and by means of the forcing pumps H, H, the operation of which has already been described, the water is raised through the valves above I I, and driven through the valves A, A into the large vessel LMM, where the included air is condensed. Into this vessel is inserted the tube YY, communicating with the leathern hose which carries off the water. The elasticity of the condensed air in the vessel LMM pressing upon the surface of the water in that vessel, forces it up through the tube YY into the leathern pipe, from whose extremity it issues with great force and velocity; and as the condensed air is continually pressing upon the water in the air-vessel, the stream will be constant and uniform.

Newsham's fire-engine. 370. A section of the fire-engine, as improved by Mr Newsham, is represented in fig. 109, where TU and WX are the forcing pumps corresponding with H, H in fig. 108,

Fig. 109.



YZ the large vessel corresponding with LMM, and *ef* the tube corresponding with YY. The vessels TU, WX, YZ, the horizontal canals ON, QP, ML, and the vertical canal EE, all communicate with each other by means of four valves O, I, K, P opening upwards, and the vertical pipe is immersed in the water to be raised. When the piston R is raised by means of the double lever $\alpha\beta$, a vacuum would be made in the barrel TU, if the water at R were prevented from rising; but as this barrel communicates with the vessel of water below EF, on the surface of which the pressure of the atmosphere is exerted, the water will rise through EF, force open the valve H, and follow the piston R. By depressing the piston R, however, the water is driven down the barrel, closes the valve H, and rushes through the valve I into the air-vessel YZ. The very same operation is going on with the pump WX, which forces the water into the air-vessel through the valve K. By these means the air-vessel is constantly filling with water, and the included air undergoing continual condensation. The air thus compressed, reacts upon the surface YZ of the water, and forces it through the tube *ef* to the stop-cock *eg*, whence, after turning the cock, the water passes into the tube *h*, fixed to a ball and socket, by which it may be discharged in any direction.

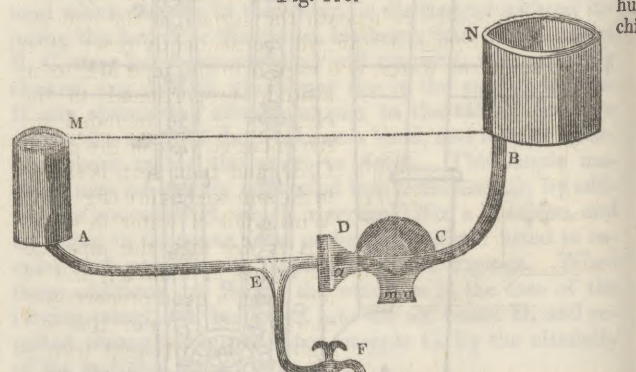
371. The fire-engine has undergone various alterations and improvements from Bramah, Dickenson, Simpkin, Raventree, Philips, and Furst, an account of whose engines may be seen in the *Repertory of Arts*, &c. A very simple and cheap fire-engine has been invented by Mr B. Dearborn, and is described in the *American Transactions* for 1794, and in *Gregory's Mechanics*, vol. ii. p. 177. Referen[ces] to the i[m]provements.

SECT. III. *On Whitehurst's Machine, and Montgolfier's Hydraulic Ram.*

372. Mr Whitehurst[1] was the first who suggested the ingenious idea of raising water by means of its momentum. A machine upon the same principle as Mr Whitehurst's, but in an improved form, has lately made its appearance in France, and excited considerable attention both on the Continent and in this country. Whatever credit, therefore, has been given to the inventor of the hydraulic ram, justly belongs to our countrymen Mr Whitehurst, and Montgolfier is entitled to nothing more than the merit of an improver. The id[ea] of raisi[ng] water b[y] its own [mo]mentu[m] first su[g]gested [by] Mr W[hite]hurst.

373. Mr Whitehurst's machine, which was actually erected at Oulton in Cheshire, is represented in fig. 110, where Descr[ip]tion o[f] Whit[e]hurst'[s ma]chine.

Fig. 110.



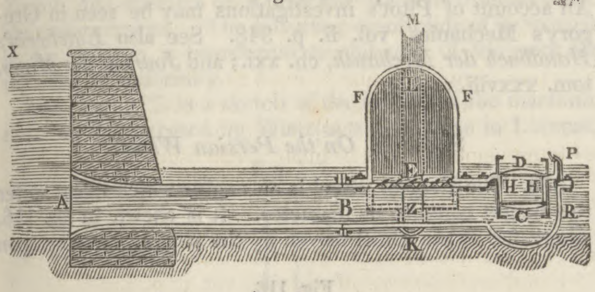
AM is the original reservoir, having its surface in the same horizontal line with the bottom of the reservoir BN. The diameter of the main pipe AE is one inch and a half, and its length about 200 yards; and the branch pipe EF is of such a size that the height of the surface M of the reservoir is nearly 16 feet above the cock F. In the valve box D is placed the valve *a*, and into the air-vessel C are inserted the extremities *m*, *n* of the main pipe, bent downwards to prevent the air from being driven out when the water is forced into it. Now as the cock F is 16 feet below the reservoir AM, the water will issue from F with a velocity

[1] *Philosophical Transactions*, 1775.

of nearly 30 feet per second. As soon as the cock F therefore is opened, a column of water 200 yards long is put in motion, and though the aperture of the cock F be small, this column must have a very considerable momentum. Let the cock F be now suddenly stopped, and the water will rush through the valve a into the air-vessel C, and condense the included air. This condensation must take place every time the cock is shut, and the imprisoned air being in a state of high compression, will react upon the water in the air-vessel, and raise it into the reservoir BN.

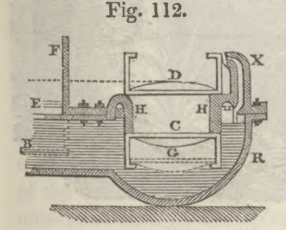
374. A section of the hydraulic ram of Montgolfier is exhibited in fig. 111, where X is the reservoir, XA the

Fig. 111.



height of the fall, and AB the horizontal canal which conveys the water to the engine MFKR. C and D are two valves, and ME a pipe reaching within a very little of the bottom E. Let us now suppose that water is permitted to descend from the reservoir. It will evidently rush along AB, and out at HH, which can be shut by the valves C or D. When the passage HH is shut by the rise of the valve C, the water is suddenly checked, and, unable to escape at HH, it will rush forwards to Z and raise the valves at E. A portion of water being thus admitted into the vessel FF, the impulse of the column of fluid is spent, the valves D and C fall, and the water issues at HH as before; when its motion is again checked, and the same operation repeated which has now been described. Whenever, therefore, the valve C closes, a portion of water will force its way into the vessel FF, and condense the air which it contains, for the included air has no communication with the atmosphere after the bottom of the pipe ME is beneath the surface of the injected water. This condensed air will consequently react upon the surface of the water, and raise it in the pipe ME to an altitude proportioned to the elasticity of the included air. An enlarged view of the valves C, D, and their seat, is shewn in the annexed figure (fig. 112). With a fall of water in which XA is *five* feet, the pipe AB *six* inches in diameter, and 14 feet long, a good proportioned ram will raise water 100 feet high. When wrought with a power of 70 cubic feet of water in the minute, it will raise $2\frac{1}{2}$ cubic feet of water per minute to the height of 100 feet. One of these machines is stated to have raised 100 hogsheads of water in 24 hours to the height of 134 feet, and a fall of only $4\frac{1}{2}$ feet. From this description it will be seen, that the only difference between the engines of Montgolfier and Whitehurst is, that the one requires a person to turn the cock, while the other has the advantage of acting spontaneously. Montgolfier[1] assures us, that the honour of this invention does not belong to England, but that he is the sole inventor, and did not receive a hint from any person whatever.—It would appear from some experiments made by Montgolfier, that the effect of the water-ram is equal to between a half and three-fourths of the power expended, which renders it superior to most hydraulic machines.[2]

Fig. 112.

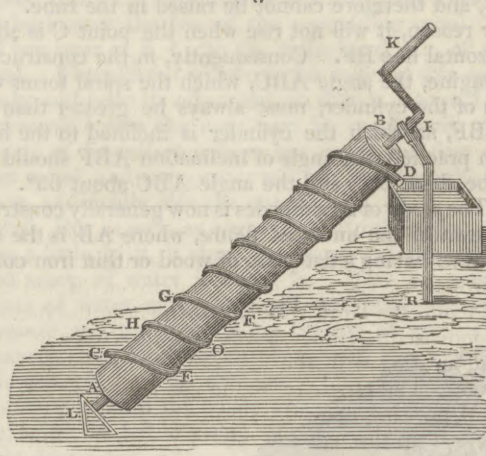


Sect. IV. *On Archimedes's Screw-Engine.*

Description of Archimedes's screw-engine.

375. The screw-engine invented by Archimedes is represented in fig. 113, where AB is a cylinder with a flexible pipe, CEHOGF, wrapped round its circumference like a screw. The cylinder is inclined to the horizon, and supported at one extremity by the bent pillar IR, while its other extremity, furnished with a pivot, is immersed in the

Fig. 113.

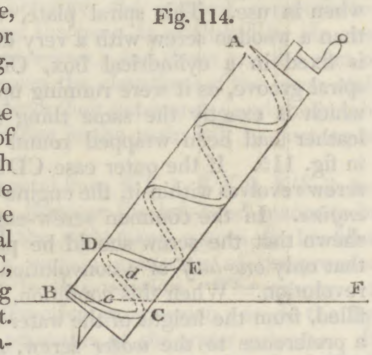


water. When, by means of the handle K, the cylinder is made to revolve upon its axis, the water which enters the lower orifice of the flexible pipe is raised to the top, and discharged at D. On some occasions, when the water to be raised moves with a considerable velocity, the engine is put in motion by a number of floatboards fixed at L, and impelled by the current; and if the water is to be raised to a great height, another cylinder is immersed in the vessel D, which receives the water from the first cylinder, and is driven by a pinion fixed at I. In this way, by having a succession of screw-engines, and a succession of reservoirs, water may be raised to any altitude. An engine of this kind is described in Ferguson's Lectures, vol. ii. p. 113.

Operation of the screw-engine.

376. In order to explain the reason why the water rises in the spiral tube, let AB be a section of the engine, BCdDE the spiral tube, BF a horizontal line or the surface of the stagnant water which is to be raised, and ABF the angle which the axis of the cylinder makes with the horizon. Then, the water which enters the extremity B of the spiral tube will descend to C, and remain there as long as the cylinder is at rest. But if a motion of rotation be communicated to the cylinder, so that the lowest part C of the spiral BCD moves towards B, and the points d, D, E towards C, and become successively the lowest parts of the spiral, the water must occupy successively the

Fig. 114.



---

[1] *Cette invention n'est point originaire d'Angleterre, elle appartient toute entiere à la France. Je declare que j'en suis le seul inventeur, et que l'idée ne m'en a eté fournie par personnes.* Journal des Mines, vol. xiii. No. 73.

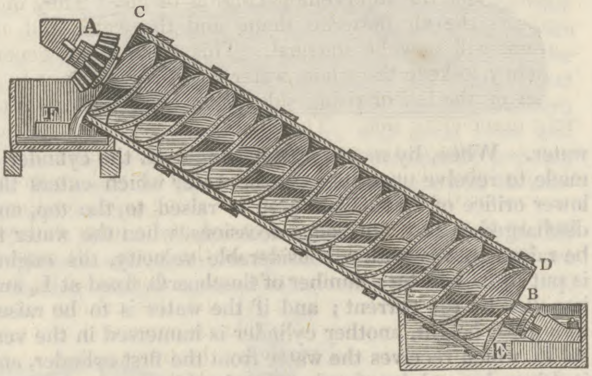
On Machines for raising water.

points d, D, E, and therefore rise in the tube; or, which is the same thing, when the point C moves to c, the point d will be at C; and as the water at C cannot rise along with the point C to c, on account of the inclination of Cc to the horizon, it must occupy the point d of the spiral, when C has moved to c; that is, the water has a tendency to occupy the lower parts of the spiral, and the rotatory motion withdraws this part of the spiral from the water, and causes it to ascend to the top of the tube. By wrapping a cord round a cylinder, and inclining it to the horizon, so that the angle ABC may be greater than the angle ABF, and then making it revolve upon its axis, the preceding remarks will be clearly illustrated.—If the direction of the spiral BC should be horizontal, that is, if it should coincide with the line BF, the water will have no tendency to move towards C, and therefore cannot be raised in the tube. For a similar reason, it will not rise when the point C is above the horizontal line BF. Consequently, in the construction of this engine, the angle ABC, which the spiral forms with the side of the cylinder, must always be greater than the angle ABF, at which the cylinder is inclined to the horizon. In practice, the angle of inclination ABF should generally be about 50°, and the angle ABC about 65°.

377. The screw of Archimedes is now generally constructed as shewn in the annexed figure, where AB is the axis of the screw, having a flat plate of wood or thin iron coiled,

Fig. 115.



as it were, round the axis, like a spiral, or the threads of a screw. The plane of this plate is perpendicular to the surface of the cylindrical axis AB, but is inclined to the direction of the axis at an angle which must always be greater than the angle which the axis AB forms with the horizon when in use. This spiral plate, which is nothing more than a wooden screw with a very deep and narrow thread, is fixed in a cylindrical box, CDEF, so as to form a spiral groove, as it were running up the tube from B to A, which is exactly the same thing as if a pipe of lead or leather had been wrapped round the cylindrical axis, as in fig. 115. If the outer case CDEF is fixed so that the screw revolves within it, the engine is called a *water screw-engine.* In the common screw-engine, Mr Eytelwein has shewn that the screw should be placed in such a manner that only *one-half* of a convolution may be filled at each revolution. When this condition, however, cannot be fulfilled, from the height of the water being variable, he gives a preference to the *water* screw, notwithstanding that in this case one-third of the water generally runs back, and the screw is apt to become clogged by impurities or weeds.

378. In a screw-engine erected at the Hurlet Alum Works, for raising the alum liquor, the length of the screw is 127 feet, its inclination to the horizon 37° 36′; the height to which it raises the liquor 76 feet 9 inches, the octagonal axis of the screw 8 inches in diameter, the diameter of the spiral 22 inches, the thickness of the covering 2 inches, the distance of the threads 9 inches, the number of the threads 168, the thickness of the spiral 2 inches, the width and depth of the spiral tube 7 inches each. The screw is sustained upon five sets of pivots or rollers, each set consisting of two rollers. The engine is driven by a water-wheel, which performs *one* revolution while the screw performs *two.* The quantity of liquor raised is 70 wine gallons; and as its specific gravity is 1.065, the quantity discharged in an hour is 17 tons. The screw is built wholly of wood, as the alum liquor acts upon iron.

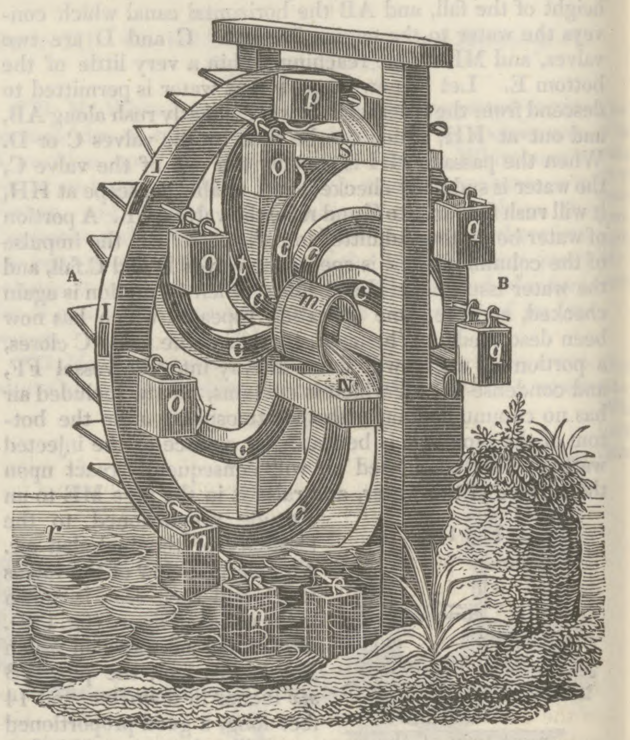
379. The theory of this engine is treated at great length by Hennert, in his *Dissertation sur la vis d'Archimede*, Berlin, 1767; by Pitot, in the *Memoirs of the French Academy*; and by Euler, in the *Nov. Comment. Petrop.* tom. v. An account of Pitot's investigations may be seen in Gregory's Mechanics, vol. ii. p. 348. See also *Eytelwein's Handbuch der Mechanik*, ch. xxi.; and *Journal des Mines*, tom. xxxviii. p. 321.

Sect. V. *On the Persian Wheel.*

Description of the Persian Wheel.

380. The Persian wheel is an engine which raises water to a height equal to its diameter. It is shewn in fig. 116, where AB is the wheel driven by the stream r acting upon

Fig. 116.



floatboards fixed on one side of its rim. A number of buckets, n, o, p, q, are disposed on the opposite side of the rim, and suspended by strong pins. When the wheel is in motion, the descending buckets q, q immerge into the stream, and ascend full of water till they reach the top at p, where they strike against the extremity of the fixed reservoir S, and being overset, discharge their contents into that reservoir. As soon as the bucket quits the reservoir, it resumes its perpendicular position by its own weight and descends as before. On each bucket is fixed a spring t, t, which moves over the top of the bar fastened to the reservoir S. By this means the bottom of the bucket is raised above the level of its mouth, and its contents completely discharged.

381. On some occasions the Persian wheel is made to

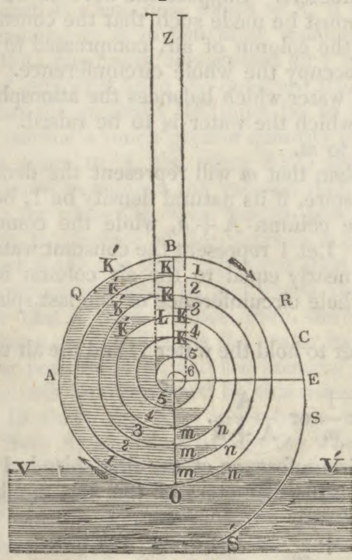
raise water only to the height of its axle. In this case, instead of buckets, its spokes, C, C, C, C, &c., are made of a spiral form, and hollow within, so that their inner extremities all terminate in the box N on the axle, and their outer extremities in the circumference of the wheel. When the rim AB, therefore, is immersed in the stream, the water runs into the tubes I, I, &c., rises in the spiral spokes C, C, C, &c., and is discharged from the orifices within *m* into the reservoir N, from which it may be conveyed in pipes.

Sect. VI. *On the Zurich Machine.*

382. This machine is a kind of pump invented and erected by H. Andreas Wirtz, an ingenious tin-plate worker in Zurich, and operates on a principle different from all other hydraulic engines. The following description of it, written by Dr Robison, is transferred to this part of the work for the sake of uniformity.

383. Fig. 117. is a sketch of the section of the machine, as it was first erected by Wirtz at a dye-house in Limmat,

Fig. 117.



in the suburbs or vicinity of Zurich. It consists of a hollow cylinder, like a very large grindstone, turning on a horizontal axis, and partly plunged in a cistern of water. The axis is hollow at one end, and communicates with a perpendicular pipe CBZ, part of which is hid by the cylinder. This cylinder or drum is formed into a spiral canal by a plate coiled up within it like the main-spring of a watch in its box; only the spires are at a distance from each other, so as to form a conduit for the water of uniform width. This spiral partition is well joined to the two ends of the cylinder, and no water escapes between them. The outermost turn of the spiral begins to widen about three-fourths of a circumference from the end, and this gradual enlargement continues from Q to S nearly a semicircle: this part may be called the Horn. It then widens suddenly, forming a Scoop or shovel SS′. The cylinder is supported so as to dip several inches into the water, whose surface is represented by VV′.

384. When this cylinder is turned round its axis in the direction ABEO, as expressed by the two darts, the scoop SS′ dips at V′ and takes up a certain quantity of water before it immerges again at V. This quantity is sufficient to fill the taper part SQ, which we have called the Horn; and this is nearly equal in capacity to the outermost uniform spiral round.

385. After the scoop has emerged, the water passes along the spiral by the motion of it round the axis, and drives the air before it into the rising-pipe, where it escapes.—In the mean time, air comes in at the mouth of the scoop; and when the scoop again dips into the water, it again takes in a similar quantity. Thus there is now a part filled with water and a part filled with air. Continuing this motion, we shall receive a second round of water and another of air. The water in any turn of the spiral will have its two ends on a level; and the air between the successive columns of water will be in its natural state; for since the passage into the rising pipe or Main is open, there is nothing to force the water and air into any other position. But since the spires gradually diminish in their length, it is plain that the column of water will gradually occupy more and more of the circumference of each. At last it will occupy a complete turn of some spiral that is near the centre; and when sent farther in, by the continuance of the motion, some of it will run back over the top of the succeeding spiral. Thus it will run over at K 4 into the right-hand side of the third spiral. Therefore it will push the water of this spire backwards, and raise its other end, so that it also will run over backwards *before* the next turn be completed. And this change of disposition will at last reach the first or outermost spiral, and some water will run over into the horn and scoop, and finally into the cistern.

On Machines for raising Water.

386. But as soon as water gets into the rising pipe, and rises a little in it, it stops the escape of the air when the next scoop of water is taken in. Here are now two columns of water acting against each other by hydrostatic pressure and the intervening column of air. They must compress the air between them, and the water and air-columns will now be unequal. This will have a general tendency to keep the whole water back, and cause it to be higher on the left or rising side of each spire than on the right descending side. The excess of height will be just such as produces the compression of the air between that and the preceding column of water. This will go on increasing as the water mounts in the rising pipe; for the air next to the rising pipe is compressed at its inner end with the weight of the whole column in the main. It must be as much compressed at its outer end. This must be done by the water column without it; and this column exerts this pressure partly by reason that *its* outer end is higher than its inner end, and partly by the transmission of the pressure on its outer end by air, which is similarly compressed from without. And thus it will happen that each column of water, being higher at its outer than at its inner end, compresses the air on the water column beyond or within it, which transmits this pressure to the air beyond it, adding to it the pressure arising from its own want of level at the ends. Therefore, the greatest compression, viz. that of the air next the main, is produced by *the sum of all the transmitted pressures;* and these are the sum of all the differences between the elevations of the inner ends of the water columns above their outer ends: and the height to which the water will rise in the main will be just equal to this sum.

387. Draw the horizontal lines K′K 1, K′K 2, K′K 3, &c. and *mn*, *mn*, *mn*, &c. Suppose the left-hand spaces to be filled with water, and the right-hand spaces to be filled with air. There is a certain gradation of compression which will keep things in this position. The spaces evidently decrease in arithmetical progression; so do the hydrostatic heights and pressures of the water columns. If, therefore, the air be dense in the same progression, all will be in hydrostatical equilibrium. Now this is evidently producible by the mere motion of the machine; for since the density and compression in each air column is supposed inversely as the bulk of the column, the absolute quantity of air is the same in all; therefore the column first taken in will pass gradually inwards, and the increasing compression will cause it to occupy precisely the whole right-hand side

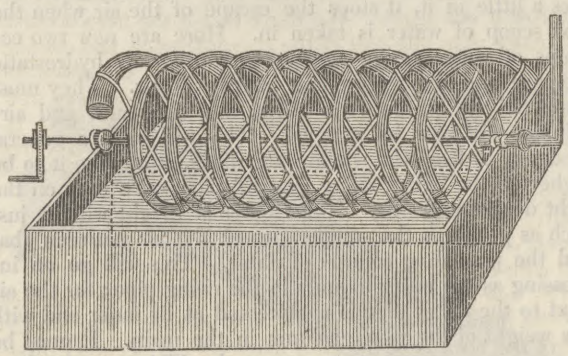
On Machines for raising Water.

of every spire. The gradual diminution of the water columns will be produced during the motion by the water running over backwards at the top, from spire to spire, and at last coming out by the scoop.

388. It is evident that this disposition of the air and water will raise the water to the greatest height, because the hydrostatic height of each water column is the greatest possible, viz. the diameter of the spire. This disposition may be obtained in the following manner: Take CL to CB as the density of the external air to its density in the last column next the rising pipe or main; that is, make CL to CB as 33 feet (the height of the column of water which balances the atmosphere), to the sum of 33 feet and the height of the rising pipe. Then divide BL into such a number of turns, that the sum of their diameters shall be equal to the height of the main; then bring a pipe straight from L to the centre C. The reason of all this is very evident.

389. But when the main is very high, this construction will require a very great diameter of the drum, or many turns of a very narrow pipe. In such cases it will be much better to make the spiral in the form of a cork-screw, as in fig. 118. instead of this flat form like a watch-spring. The

Fig. 118.



pipe which forms the spiral may be lapped round the frustum of a cone, whose greatest diameter is to the least (which is next to the rising pipe) in the same proportion that we assigned to CB and CL. By this construction the water will stand in every round so as to have its upper and lower surfaces tangents to the top and bottom of the spiral, and the water columns will occupy the whole ascending side of the machine, while the air occupies the descending side.

390. This form is vastly preferable to the flat one: it will allow us to employ many turns of a large pipe, and therefore produce a great elevation of a large quantity of water.

The same thing will be still better done by lapping the pipe on a cylinder, and making it taper to the end, in such a proportion that the contents of each round may be the same as when it is lapped round the cone. It will raise the water to a greater height (but with an increase of the impelling power) by the same number of turns, because the vertical or pressing height of each column is greater.

Nay, the same thing may be done in a more simple manner, by lapping a pipe of uniform bore round a cylinder. But this will require more turns, because the water columns will have less differences between the heights of their two ends. It requires a very minute investigation to show the progress of the columns of air and water in this construction, and the various changes of their arrangement, before one is attained which will continue during the working of the machine.

391. We have chosen for the description of the machine that construction which made its principle and manner of working most evident, namely, which contained the same material quantity of air in each turn of the spiral, more and more compressed as it approaches to the rising pipe. We should otherwise have been obliged to investigate in great detail the gradual progress of the water, and the frequent changes of its arrangement, before we could see that one arrangement would be produced which would remain constant during the working of the machine. But this is not the best construction. We see that, in order to raise water to the height of a column of 34 feet, which balances the atmosphere, the air in the last spire is compressed into half its bulk; and the quantity of water delivered into the main at each turn is but half of what was received into the first spire, the rest flowing back from spire to spire, and being discharged at the spout.

392. But it may be constructed so as that the quantity of water in each spire may be the same that was received into the first; by which means a greater quantity (double in the instance now given) will be delivered into the main, and raised to the same height by very nearly the same force.—This may be done by another proportion of the capacity of the spires, whether by a change of their caliber or of their diameters. Suppose the bore to be the same, the diameter must be made such that the constant column of water, and the column of air, compressed to the proper degree, may occupy the whole circumference. Let A be the column of water which balances the atmosphere, and h the height to which the water is to be raised. Let A be to $A+h$ as 1 to m.

393. It is plain that m will represent the density of the air in the last spire, if its natural density be 1, because it is pressed by the column $A+h$, while the common air is pressed by A. Let 1 represent the constant water column, and therefore nearly equal to the air column in the first spire. The whole circumference of the last spire must be $1+\frac{1}{m}$, in order to hold the water 1, and the air compressed into the space $\frac{1}{m}$ or $\frac{A}{A+h}$.

394. The circumference of the first spire is $1+1$ or 2. Let D and d be the diameters of the first and last spires; we have $2:1+\frac{1}{m}=D:d$, or $2\,m:m+1=D:d$. Therefore, if a pipe of uniform bore be lapped round a cone, of which D and d are the end diameters, the spirals will be very nearly such as will answer the purpose. It will not be quite exact, for the intermediate spirals will be somewhat too large. The conoidal frustum should be formed by the revolution of a curve of the logarithmic kind. But the error is very trifling.

With such a spiral, the full quantity of water which was confined in the first spiral will find room in the last, and will be sent into the main at every turn. This is a very great advantage, especially when the water is to be much raised. The saving of power by this change of construction is always in proportion to the greatest compression of the air.

The great difficulty in the construction of any of these forms is in determining the form and position of the horn and the scoop; and on this greatly depends the performance of the machine. The following instructions will make it pretty easy.

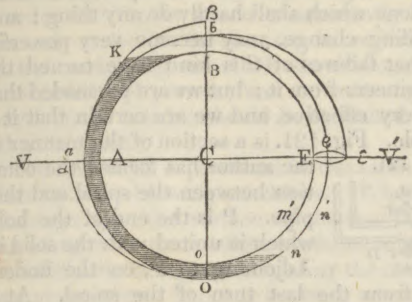
395. Let ABEO (fig. 119.) represent the first or outermost round of the spiral, of which the axis is C. Suppose it immerged up to the axis in the water VV, we have seen that the machine is most effective when the surfaces KB and O n of the water columns are distant the whole diameter BO of the spiral. Therefore, let the pipe be first supposed of equal calibre to the very mouth E e, which we suppose to be just about to dip into the water. The sur-

Fig. 1[19.]

On Machines for raising Water.

face O n is kept there, in opposition to the pressure of the water column BAO, by the compressed air contained in

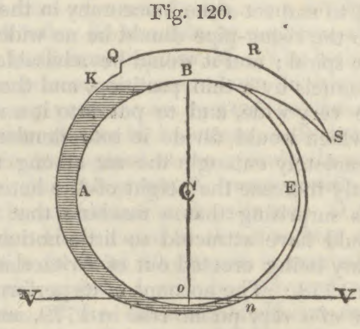
Fig. 119.



the quadrant OE, and in the quadrant which lies behind EB. And this compression is supported by the columns behind, between this spire and the rising pipe. But the air in the outermost quadrant EB is in its natural state, communicating as yet with the external air. When, however, the mouth E ε has come round to A, it will not have the water standing in it in the same manner, leaving the half space BEO filled with compressed air; for it took in and confined only what filled the quadrant BE. It is plain, therefore, that the quadrant BE must be so shaped as to take in and confine a much greater quantity of air; so that when it has come to A, the space BEO may contain air sufficiently dense to support the column AO. But this is not enough: for when the wide mouth, now at A α, rises up to the top, the surface of the water in it rises also, because the part Ao O a is more capacious than the cylindric part OE $e\,o$ which succeeds it, and which cannot contain all the water that it does. Since, then, the water in the spire rises above A, it will press the water back from O n to some other position $m'\,n'$, and the pressing height of the water-column will be diminished by this rising on the other side of O. In short, the horn must begin to widen, not from B but from A, and must occupy the whole semicircle ABE; and its capacity must be to the capacity of the opposite cylindrical side as the sum of BO, and the height of a column of water which balances the atmosphere to the height of that column. For then the air which filled it, when of the common density, will fill the uniform side BEO, when compressed so as to balance the vertical column BO. But even this is not enough; for it has not taken in enough of water. When it dipped into the cistern at E, it carried air down with it, and the pressure of the water in the cistern caused the water to rise into it a little way; and some water must have come over at B from the other side, which was drawing narrower. Therefore, when the horn is in the position EOA, it is not full of water. Therefore, when it comes into the situation OAB, it cannot be full nor balance the air on the opposite side. Some will therefore come out at O, and rise up through the water. The horn must, therefore, 1st, Extend at least from O to B, or occupy half the circumference; and, 2dly, It must contain at least twice as much water as would fill the side BEO. It will do little harm though it be much larger; because the surplus of air which it takes in at E will be discharged, as the end E e of the horn rises from O to B, and it will leave the precise quantity that is wanted. The overplus water will be discharged as the horn comes round to dip again into the cistern. It is possible, but requires a discussion too intricate for this place, to make it of such a size and shape, that while the mouth moves from E to B, passing through O and A, the suface of the water in it shall advance from E ε to O n, and be exactly at O when the beginning or narrow end of the horn arrives there.

400. We must also secure the proper quantity of water. When the machine is so much immersed as to be up to the axis in water, the capacity which thus secures the proper quantity of air will also take in the proper quantity of water. But it may be erected so as that the spirals shall not even reach the water. In this case it will answer our purpose if we join to the end of the horn a scoop or shovel QRSB (fig. 120.), which is so formed as to take in at least

Fig. 120.



as much water as will fill the horn. This is all that is wanted in the beginning of the motion along the spiral, and more than is necessary when the water has advanced to the succeeding spire; but the overplus is discharged in the way we have mentioned. At the same time, it is needless to load the machine with more water than is necessary, merely to throw it out again. We think that if the horn occupies fully more than one-half of the circumference, and contains as much as will fill the whole round, and if the scoop lifts as much as will certainly fill the horn, it will do very well.

The scoop must be very open on the side next the axis, that it may not confine the air as soon as it enters the water. This would hinder it from receiving water enough.

401. The following dimensions of a machine erected at Florence, and whose performance corresponded extremely well with the theory, may serve as an example.

The spiral is formed on a cylinder of ten feet diameter, and the diameter of the pipe is six inches. The smaller end of the horn is of the same diameter; it occupies three-fourths of the circumference, and is $7\frac{8}{10}$ths inches wide at the outer end. Here it joins the scoop, which lifts as much water as fills the horn, which contains 4340 Swedish cubic inches, each = 1.577 English. The machine makes six turns in a minute, and raises 1354 pounds of water, or 22 cubic feet, 10 feet high in a minute.

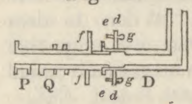
402. The above account will, we hope, sufficiently explain the manner in which this singular hydraulic machine produces its effect. When every thing is executed by the maxims which we have deduced from its principles, we are confident that its performance will correspond to the theory; and we have the Florentine machine as a proof of this. It raises more than ten-elevenths of what the theory promises, and it is not perfect. The spiral is of equal caliber, and is formed on a cylinder. The friction is so inconsiderable in this machine, that it need not be minded: but the great excellency is, that whatever imperfection there may be in the arrangement of the air and water columns, this only affects the elegance of the execution, causing the water to make a few more turns in the spiral before it can mount to the height required; but wastes no power, because the power employed is always in proportion to the sum of the vertical columns of water in the rising side of the machine; and the height to which the water is raised by it is in the very same proportion. It should be made to move very slow, that the water be not always dragged up by the pipes, which would cause more to run over from each column, and diminish the pressure of the remainder.

403. If the rising-pipe be made wide, and thus room be made for the air to escape freely up through the water, it will rise to the height assigned; but if it be narrow, so that the air cannot get up, it rises almost as slow as the

On Machines for raising Water.

water, and by this circumstance the water is raised to a much greater height mixed with air, and this with hardly any more power. It is in this way that we can account for the great performance of the Florentine machine, which is almost triple of what a man can do with the finest pump that ever was made: indeed, the performance is so great, that one is apt to suspect some inaccuracy in the accounts. The entry into the rising-pipe should be no wider than the last part of the spiral; and it would be advisable to divide it into four channels by a thin partition, and then to make the rising-pipe very wide, and to put into it a number of slender rods, which would divide it into slender channels that would completely entangle the air among the water. This will greatly increase the height of the heterogeneous column. It is surprising that a machine that is so very promising should have attracted so little notice. We do not know of any being erected out of Switzerland, except at Florence in 1778. The account of its performance was in consequence of a very public trial in 1779, and honourable declaration of its merit, by Sig. Lorenzo Ginori, who erected another, which fully equalled it. It is shortly mentioned by Professor Sulzer of Berlin, in the *Sammlungen Vermischlen Schristen* for 1754. A description of it is published by the Philosophical Society at Zurich in 1766, and in the descriptions published by the Society in London for the encouragement of Arts in 1776. The celebrated Daniel Bernoulli has published a very accurate theory of it in the Petersburgh Commentaries for 1772, and the machines at Florence were erected according to his instructions. Baron Alstromer in Sweden caused a glass model of it to be made, to exhibit the internal motions for the instruction of artists, and also ordered an operative engine to be erected; but we have not seen any account of its performance. It is a very intricate machine in its principles; and an ignorant engineer, nay the most intelligent, may erect one which shall hardly do any thing; and yet by a very trifling change, may become very powerful. We presume that failures of this kind have turned the attention of engineers from it; but we are persuaded that it may be made very effective, and we are certain that it must be very durable. Fig. 121. is a section of the manner in which the author has formed the communication between the spiral and the rising-pipe. P is the end of the hollow axis which is united with the solid iron axis. Adjoining to P, on the under side, is the entry from the last turn of the spiral. At Q is the collar which rests on the supports, and turns round in a hole of bell-metal. *f f* is a broad flanch cast in one piece with the hollow part. Beyond this the pipe is turned somewhat smaller, very round and smooth, so as to fit into the mouth of the rising-pipe, like the key of a cock. This mouth has a plate *e e* attached to it. There is another plate *d d*, which is broader than *e e*, and is not fixed to the cylindrical part, but moves easily round it. In this plate are four screws, such as *g g*, which go into holes in the plate *f f*, and thus draw the two plates *f f* and *d d* together, with the plate *e e* between them. Pieces of thin leather are put on each side of *e e;* and thus all escape of water is effectually prevented, with a very moderate compression and friction.

Fig. 121.



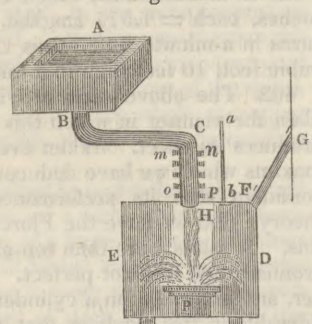
CHAPTER IV. ON MACHINES IN WHICH WATER IS THE CHIEF AGENT.

Sect. I. *On the Water-Blowing Machine.*

Description of the water-blowing machine.

404. The water blowing machine, or *trombe*, as the French call it, consists of a reservoir of water AB, fig. 122, into the bottom of which the bent leaden pipe BCH is inserted; of a condensing vessel DE, into whose top the lower extremity H of the pipe is fixed, and of a pedestal P resting on the bottom of this vessel. When the water from the reservoir AB is descending through the part CH of the pipe, it is in contact with the external air by means of the orifices or tubes *m, n, o, p;* and by the principle of the lateral communication of motion in fluids, the air is dragged along with the water. This combination of air and water issuing from the aperture H, and impinging upon the surface of the stone pedestal P, is dispersed in various directions. The air being thus separated from the water, ascends into the upper part of the vessel, and rushes through the opening F, whence it is conveyed by the pipe FG to the fire at G, while the water falls to the lower part of the vessel, and is discharged by the openings M, N. That the greatest quantity of air may be driven into the vessel DE, the water should begin to fall at C with the least possible velocity; and the height of the lowest tubes above the extremity H of the pipe should be three-elevenths of the length of the vertical tube CH, in order that the air may move in the pipe FG with sufficient velocity.

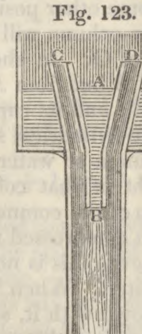
Fig. 122.



Water Blowing Machine.

405. A different form of the machine is shewn in fig. 123, where AB is the pipe of a conical form, and where the water which flows down AB is supplied with air by the pipes CB, DB.

Fig. 123.



406. In the machines of this kind used at Alvar in Dauphiny, the diameter of the conical pipe AB is 12 inches at A, and 5 at B, and only four tubes are used for admitting the air. This machine gives a powerful as well as an equal and continued blast, but the air is considered to be too moist and too cold.

Way whic wind nera

407. Fabri and Dietrich imagined that the wind is produced by the decomposition of the water, or its transformation into gas, in consequence of the agitation and percussion of its parts. But M. Venturi, to whom we owe the first philosophical account of this machine, has shewn that this opinion is erroneous, and that the wind is supplied from the atmosphere, for no wind was generated when the lateral openings *m, n, o, p* were shut. The principal object, therefore, in the construction of water-blowing machines, is to combine as much air as possible with the descending current. For this purpose the water is often made to pass through a kind of cullender placed in the open air, and perforated with a number of small triangular orifices. Through these apertures the water descends in many small streams; and by exposing a greater surface to the amosphere, it carries along with it an immense quantity of air. The water is then conveyed to the pedestal P, fig. 122, by a pipe CH opened and enlarged at C, so as to be considerably wider than the end of the tube which holds the cullender.

408. It has been generally supposed that the waterfall should be very high; but Dr Lewis has shewn, by a variety of experiments, that a fall of four or five feet is sufficient,

B[r]amah's [Pr]ess.

and that when the height is greater than this, two or more blowing machines may be erected, by conducting the water from which the air is extricated, into another reservoir, from which it again descends, and generates air as formerly. In order that the air which is necessarily loaded with moisture, may arrive at the furnace in as dry a state as possible, the condensing vessel DE should be made as high as circumstances will permit; and in order to determine the strength of the blast, it should be furnished with a gage *a b* filled with water.

Ca[us]es of th[e r]ain wi[nd].

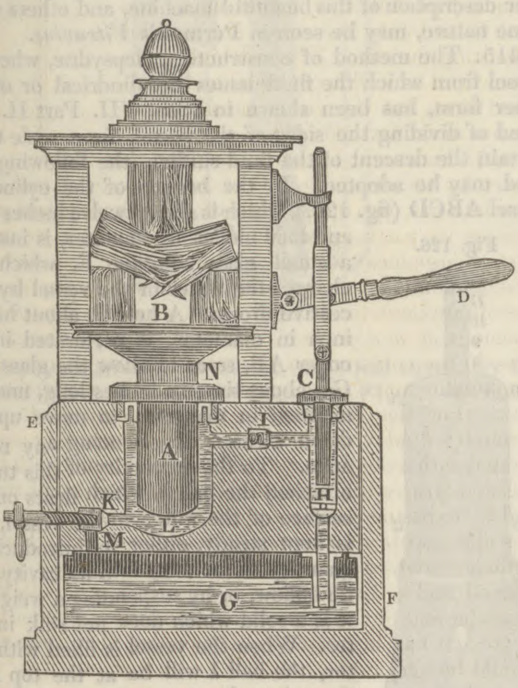
409. The rain wind is produced in the same way as the blast of air in water-blowing machines. When the drops of rain impinge upon the surface of the sea, the air which they drag along with them often produces a heavy squall, which is sufficiently strong to carry away the mast of a ship. The same phenomenon happens at land, when the clouds empty themselves in alternate showers. In this case, the wind proceeds from that quarter of the horizon where the shower is falling. The common method of accounting for the origin of the winds by local rarefaction of the air appears pregnant with insuperable difficulties; and there is reason to think that these agitations in our atmosphere ought rather to be referred to the principle which we have now been considering. The *ventaroli* which issue from volcanic mountains, arise from the air which is carried down the hollows by the falls of water. At the foot of the cascades which fall from the glazier of Roche Melon, Venturi found the force of the wind arising from the air dragged down by the water to be so strong, that it could scarcely be withstood. For farther information on this subject, the reader is referred to Lewis's *Commerce of Arts*, Wolfii *Opera Mathematica*, tom. i. p. 830, *Journal des Mines*, No. XCI. or Nicholson's *Journal*, vol. ii. 4to, p. 487, vol. xii. p. 48.

SECT. II. *Bramah's Hydrostatic Press.*

D[esc]rip-ti[on] of Bra-m[ah']s ma-ch[in]e.

410. The machine invented by Mr Bramah, depends upon the principle, that any pressure exerted upon a fluid mass is propagated equally in every direction. It is represented in fig. 124, where L is a strong metallic cylinder,

Fig. 124.



Bramah's Press.

furnished with a piston A, perfectly water-tight at the neck N. Into the side of this cylinder is inserted the end of the tube I, the interior orifice of which is closed by the valve at I. The other extremity of the tube communicates with the forcing pump DCH, by which water or other fluids may be driven into the cylinder L. The whole rests on a solid mass of masonry EF, or a firmly fixed wooden frame. A valve K, wrought by a screw, allows the water to return to G from the pipe M. The body to be crushed, broken, or pressed, is placed above the horizontal board B. Then, if any pressure is exerted on the surface of the water in the cylinder H, by means of the lever D, this pressure will be propagated to the cylinder L, and exert a certain force upon the piston A, varying with the respective areas of the sections of each cylinder. If the diameter of the cylinder H, is equal to the diameter of the cylinder L, and if a force of 10 pounds is exerted at the handle D, then the piston A will be elevated with a force of 10 pounds; if the diameter of H be one-half that of L, the piston A will be raised with a force of 40 pounds, because the area of the one piston is four times the area of the other. Or, in general, if D be the diameter of the cylinder L, d that of the cylinder H, and F the force exerted at the lever D, we shall have $d^2 : D^2 = F : \frac{F \times D^2}{d^2}$, which is the force exerted upon the piston B. Thus, if $d = 2$ inches, $D = 24$ inches, and $F = 10$ pounds, then $\frac{F \times D^2}{d^2} = \frac{10 \times 24 \times 24}{2 \times 2} = 1440$ pounds, the force with which the piston B is elevated. Now, as this force increases as d^2 diminishes, or as F and D^2 increase, there is no limit to the power of the engine; for the diameter of the cylinder L may be made of any size, and that of the cylinder H exceedingly small, while the power may be still farther augmented by lengthening the lever D. The same effects may be produced by injecting air into the pipe I by means of a large globe fixed at its extremity. Upon the same principles the power and motion of one machine may be communicated to another; for we have only to connect the two machines by means of a pipe filled with water, inserted at each extremity into a cylinder furnished with a piston. By this means the power which depresses one of the pistons will be transferred along the connecting pipe, and will elevate the other piston. In the same way water may be raised out of wells of any depth, and at any distance from the place where the power is applied; but we must refer the reader, for a detailed account of these applications, to the specification of the patent obtained by Mr Bramah, or to *Gregory's Mechanics*, vol. ii. p. 120.

SECT. III. *M. Mannoury Dectot's Dunaide.*

De[c]tot's Danaide.

411. This machine, invented by M. Mannoury Dectot of Paris, consists of a cylindrical trough of tin-plate, nearly as high as it is broad, and having a hole in the centre of its bottom. It is fixed to a vertical axis of iron, which passes through the middle of the hole in the bottom, a vacant space being left all around to permit the water to escape. The axis turns with the trough upon a pivot, and is fixed above to a collar.

A drum of tin-plate, close above and below, is fixed upon the axis of the trough, and placed within the trough, so as to be concentric with it, and to leave only between the outer circumference of the drum and the inner circumference of the trough, an annular space not exceeding $1\frac{1}{2}$ inches. This annular space communicates with a space less than $1\frac{1}{2}$ inches, left between the bottom of the drum and the bottom of the trough, and divided into compartments by diaphragms fixed upon the bottom of the trough, Dectot's Danaide.

and proceeding from the circumference to the central hole in the bottom of the trough.

The water comes from a reservoir above by one or two pipes, and makes its way into this annular space between the trough and drum. The bottom of these pipes corresponds with the level of the water in the trough, and they are directed horizontally, and as tangents to the mean circumference between that of the trough and of the drum. The velocity which the water has acquired by its fall along these pipes, makes the machine move round its axis, and this motion accelerates by degrees, till the velocity of the water in the space between the trough and drum equals that of the water from the reservoir; so that no sensible shock is perceived of the affluent water upon that which is contained in the machine.

This circular motion communicates to the water between the trough and drum a centrifugal force, in consequence of which it presses against the sides of the trough. This centrifugal force acts equally upon the water contained in the compartments at the bottom of the trough, but it acts less and less as this water approaches the centre.

The whole water then is animated by two opposite forces, viz. gravity, and the centrifugal force. The first tends to make the water run out at the hole at the bottom of the trough; the second, to drive the water from that hole.

To these two forces are joined a third, viz. *friction*, which acts here an important and singular part, as it promotes the efficacy of the machine, while in other machines it always diminishes that efficacy. Here, on the contrary, the effect would be nothing were it not for the friction, which acts as a tangent to the sides of the trough and drum.

By the combination of these three forces, there ought to result a more or less rapid flow from the hole at the bottom of the trough; and the less force the water has as it issues out, the more it will have employed in moving the machine, and of course in producing the useful effect for which it is destined.

The moving power is the weight of the water running in, multiplied by the height of the reservoir from which it flows above the bottom of the trough; and the useful effect is the same product diminished by half the force which the water retains when it issues out of the orifice below.

In order to ascertain, by direct experiment, the magnitude of this effect, MM. Prony and Carnot fixed a cord to the axis of the machine, which passing over a pulley, raised a weight by the motion of the machine. By this means, the effect was found to be $\frac{7}{10}$ of the power, and often approached $\frac{75}{100}$ without reckoning the friction of the pulleys, which has nothing to do with the machine. This effect exceeds that of the best overshot-wheels. See the *Report of the Institute,* 23d August 1813; or Thomson's *Annals of Philosophy,* vol. ii. p. 412.

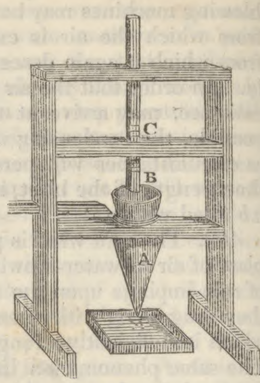
Sect. IV. *On Clepsydræ or Water-Clocks.*

History of clepsydræ.

412. A clepsydra or water-clock, derived from κλέπτω, *to steal,* and ὕδωρ, *water,* is a machine which measures time by the motion of water. The invention of this machine has been ascribed to Scipio Nasica, the cousin of Scipio Africanus, who flourished about two hundred years before the Christian era. It was well known, however, at an earlier period, among the Egyptians, who employed it to measure the course of the sun. It is highly probable that Scipio Nasica had only the merit of introducing it into his native country. These machines were in use for a very long period, and continued to be employed as measurers of time till the invention of the pendulum clock enriched the arts and sciences.

413. The earliest, and probably the simplest water-clock, consisted of a hollow cone A (fig. 125), perforated at its apex, and of a solid cone B, which exactly fitted the interior of A. The aperture of the cone A was of such a size in relation to the contents of A, that it discharged all the water in A in the course of the shortest day in winter. The length of the cone was divided into *twelve* parts, which indicated the hours as the water was discharged. As the day became longer, the line in which the water was discharged required to be increased; and, in order to effect this, the solid cone B was introduced into the hollow cone A, and, in proportion to the depth of its immersion, the water flowed with less facility, and more slowly, from the aperture at the vertex of the cone A. By this means the time of emptying the cone was accommodated to the varying length of the day, and the adjustment for this purpose was made by a graduated scale BC, upon the handle of the solid cone.

Fig 125.



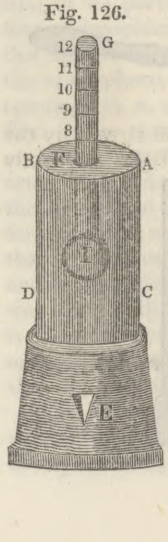
Clepsydr

The clepsydra of Ctesibii

413. The clepsydra, invented by Ctesibius of Alexandria, was an interesting machine. The water, which indicated the progress of time by the gradual descent of its surface, flowed in the form of tears from the eyes of the human figure. Its head was bent down with age: its look was dejected, while it seemed to pay the last tribute of regret to the fleeting moments as they passed. The water which was thus discharged was collected in a vertical reservoir, where it raised another figure, holding in its hand a rod, which, by its gradual ascent, pointed out the hours upon a vertical column. The same fluid was afterwards employed in the interior of the pedestal, as the impelling power of a piece of machinery, which made this column revolve round its axis in a year, so that the months and the days were always shewn by this index, whose extremity described a vertical line divided according to the relative lengths of the hours of day and night. Among the ancients the length of the hours varied every day, and even the hours of the day differed in length from those of the night; for the length of the day, or the interval between sunrise and sunset, was always divided into twelve equal parts, while the length of the night, or the interval between sunset and sunrise, was divided into the same number of parts, for hours. A farther description of this beautiful machine, and others of the same nature, may be seen in Perrault's *Vitruvius.*

415. The method of constructing clepsydræ, when the vessel from which the fluid issues is cylindrical or of any other form, has been shewn in Prop. VII. Part II. Instead of dividing the sides of the vessel, for a scale to ascertain the descent of the fluid surface, the following method may be adopted. In the bottom of the cylindrical vessel ABCD (fig. 126.), which is about twelve inches high, and four inches in diameter, is inserted a small glass adjutage E, which discharges the water in the vessel by successive drops. A hole F, about half an inch in diameter, is perforated in the cover AB, so as to allow the glass tube GI, about sixteen inches long, and half an inch in diameter, to move up and down without experiencing any resistance. To the extremity of this tube is attached the ball I, which floats on the surface of the water in the vessel, and is kept steady, either by introducing a quantity of mercury into its cavity, if it be hollow, or by suspending a weight, if it is a solid which does not sink in water. When the vessel is filled with water, the ball I will be at the top AB; then, in order to graduate the tube C,

Fig. 126.



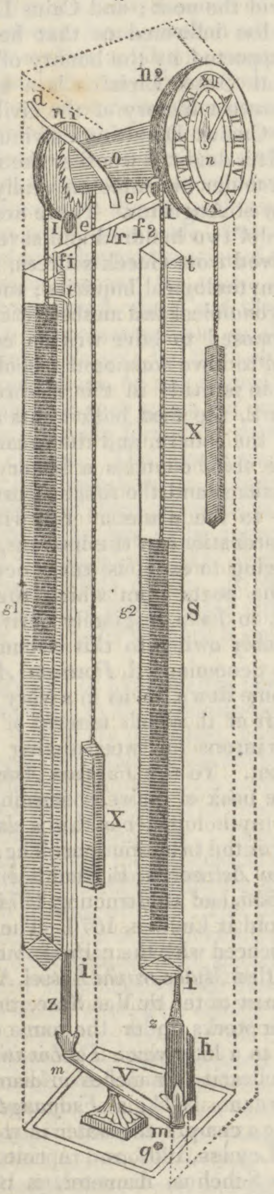
Clepsydræ.

let the water flow out at E, and by means of a watch mark the points on the tube, which descend to F after the lapse of every hour, and every quarter, and the instrument will be finished. In order to use this hydroscope or water-clock, pour into the vessel ABCD till the hour of the day is about to descend below F; and when this is done, it will point out any succeeding hour till the vessel is emptied.

Hamilton's clepsydra.

359. The clepsydra, invented by the honourable Mr Charles Hamilton, is represented in fig. 127. An open

Fig. 127.



canal ee, supplied with a constant and equal stream by the syphon d, has at each end ff, open pipes $f1$, $f2$, of exactly equal bores, which deliver the water that runs along the canal e, alternately into the vessels $g1$, $g2$, in such a quantity as to raise the water from the mouth of the tantalus t, exactly in an hour. The canal ee is equally poised by the two pipes $f1$, $f2$, upon a centre r; the ends of the canal e are raised alternately, as the cups zz are depressed, to which they are connected by the lines running over the pulleys ll. The cups zz are fixed at each end of the balance mm, which moves up and down upon its centre v. $n1$, $n2$, are the edges of two wheels or pulleys, moving different ways alternately, and fitted to the cylinder o by oblique teeth, both in the cavity of the wheel and upon the cylinder, which, when the wheel n moves one way, that is, in the direction of the minute-hand, meet the teeth of the cylinder, and carry the cylinder along with it, and slip over those of the cylinder when n moves the contrary way, the teeth not meeting, but receding from each other. One or other of these wheels nn continually moves o in the same direction, with an equable and uninterrupted motion. A fine chain goes twice round each wheel, having at one end a weight X, always out of the water, which equiponderates with y at the other end, when kept floating on the surface of the fluid in the vessel g, which y must always be; the two cups z, z, one at each end of the balance, keep it in equilibrio, till one of them is forced down by the weight and impulse of the water, which it receives from the tantalus ti. Each of these cups z, z, has likewise a tantalus of its own h, h, which empties it after the water has run from g, and leaves the two cups again in equilibrio: q is a drain to carry off the water. The dial-plate, &c. needs no description. The motion of the clepsydra is effected thus: As the end of the canal ee, fixed to the pipe $f1$, viz. the lowest in the figure, all the water supplied by the syphon runs through the pipe $f1$, into the vessel $g1$, till it runs over the top of the tantalus t; when it immediately runs out at i, into the cup Z, at the end of the balance m, and forces it down; the balance moving on its centre V. When one side of m is brought down, the string which connects it to $f1$, running over the pulley l, raises the end $f1$, of the canal e, which turns upon its centre r, higher than $f2$; consequently, all the water which runs through the syphon d, passes through $f2$ into $g2$, till the same operation is performed in that vessel, and so on alternately. As the height to which the water rises in g in an hour, viz. from S to t, is equal to the circumference of n, the float y rising through that height along with the water, allows the weight X to act upon the pulley n, which carries with it the cylinder o; and this, making a revolution, causes the index k to describe an hour on the dial-plate. This revolution is performed by the pulley $n1$; the next is performed by $n2$, whilst $n1$ goes back, as the water in $g1$ runs out through the tantalus; for y must follow the water, as its weight increases out of it. The axis o always keeps moving the same way; the index p describes the minutes; each tantalus must be wider than the syphon, that the vessels gg may be emptied as low as S, before the water returns to them.

360. For farther information respecting subjects connected with hydrodynamics, see MECHANICS, RESISTANCE *of Fluids*, WATER-*Works*, &c. (N. N. N.)

HYDROGRAPHICAL CHARTS or MAPS, usually called sea-charts, are projections of some part of the sea or coast, for the use of navigation. In these are laid down all the rhumbs or points of the compass, the meridians, parallels, &c. with the coasts, capes, islands, rocks, shoals, shallows, &c. in their proper places and proportions.

HYDROGRAPHY, the art of measuring and describing the sea, rivers, canals, lakes, and the like. With regard to the sea, it gives an account of its tides, countertides, soundings, bays, gulfs, creeks, as also of the rocks, shelves, sands, shallows, promontories, and harbours; the distance and bearing of one port from another; with every thing that is remarkable, whether out at sea or on the coast.

HYDROMEL, honey diluted in nearly an equal weight of water. When this liquor has not fermented, it is called *simple hydromel;* and when it has undergone the spirituous fermentation, it is called the *vinous hydromel* or *mead.*

HYDROMETER, an instrument for measuring the gravity, density, &c. of water and other fluids. For an account of different hydrometers, see the article HYDRODYNAMICS.

HYDROPHANES, or OCULUS MUNDI, a kind of precious stone, which becomes transparent in water. It was much esteemed by the ancients.

HYDROPHOBIA, literally an aversion to or dread of water, a terrible symptom of the *rabies canina,* and which has likewise been found to take place in violent inflammations of the stomach, as well as in hysterical fits.

HYDROPHYLACIA, a word used by Kircher and some others to express those great reservoirs of water which, as he supposed, were placed in the Alps and other mountains for the supply of the rivers which run through the lower countries. The formation of these reservoirs he considers as one of the great uses of mountains in the economy of the universe.

HYDROSCOPE, an instrument anciently used for measuring time. The hydroscope was a kind of water-clock, consisting of a cylindrical tube, conical at the bottom. The cylinder was graduated, or marked with divisions, to which the top of the water becoming successively continuous, as it trickled out at the vertex of the cone, indicated the hour.

HYDROSTATICS is that branch of physics which treats of the weight, pressure, and equilibrium of fluids. See HYDRODYNAMICS.

HYDROTHORAX, a collection of water in the chest.

HYDRUNTUM, in *Ancient Geography,* a noble and commodious port of Calabria, from which there was a shorter passage to Apollonia. It was famous for its antiquity, and for the fidelity and bravery of its inhabitants. It is now Otranto, a city of Naples, situated at the entrance of the Gulf of Venice. Long. 19. 15. E. Lat. 40. 12. N.

HYEMANTES, in the primitive church, were offenders who had been guilty of so great enormities, that they were not allowed to enter the porch of the churches with the other penitents, but were obliged to stand without, exposed to all the inclemency of the weather.

HYGEIA, in *Mythology.* See HEALTH.

HYGIEINE, Ὑγιεινη, formed from ὑγιης, *sound* or *healthy,* that branch of medicine which relates to health, and discovers proper means for the preservation of that state.

HYGIEINE, more largely taken, is divided into three parts: *prophylactice,* which foresees and prevents diseases; *synteritice,* which is employed in preserving health; and *analeptice,* which relates to the cure of diseases, and the restoration of health.

HYGINUS, CAIUS JULIUS, an ancient Latin writer, who flourished in the time of Augustus. Suetonius, in his work *De Illustribus Grammaticis,* says that he was by birth a Spaniard; but some think that he was a native of Alexandria in Egypt. He was originally a slave of Julius Cæsar, who brought him to Rome; but having distinguished himself by his literary acquirements, he was emancipated by Augustus, and placed at the head of the library which that sovereign had founded in the temple of the Palatine Apollo. Whilst in this situation, he became intimate with Ovid the poet; and Caius Licinius, a man of consular rank, has informed us that he died very poor, having been supported by the bounty of his friends; but some think that Caius Licinius is a mistake for Caius Asinius, who wrote a history of the civil war, and served as consul with Cneius Domitius Calvinus, in the year of the city 723. It is doubtful whether the works which have been preserved under his name are really the productions of the freedman of Augustus. These are *Fabularum Liber,* a collection of two hundred and seventy-seven fables, principally derived from Greek sources, and which are of great value in mythological inquiries; and *Poeticon Astronomicon,* an astronomical and mathematical work in prose. He is also supposed to have written on the subject of agriculture, and to have composed a book of Genealogies, of which mention is made in the *Poeticon Astronomicon.* Of this last work, the first book treats of the world and the doctrine of the sphere, and the second of the signs in the zodiac; the third contains a history and description of the constellations, and the fourth treats of the several things relating to the planets. But whilst Hyginus describes the constellations in the heavens, and enumerates the stars belonging to each, he takes occasion to explain the fables of the poets from which these constellations were supposed to have originally derived their names, and it is probably owing to this circumstance that the work has been denominated *Poeticon Astronomicon.* It has however come down to us in a very imperfect state; and all that part of it which treated of the month, the year, and the reasons for intercalating the months, has been entirely lost. To the *Poeticon Astronomicon* is usually appended a book of fables, containing a compendium of the heathen mythology; but this is also imperfect, and is moreover suspected to be spurious. The *Liber Fabularum* and the *Poeticon Astronomicon* have been published together at Basle, 1555, and at Hamburg, 1674; and separately at Paris, 1578, and at Leyden, 1670. The best editions are those which appeared with the commentary of Muncker, in a collection entitled *Mythographi Latini,* Amsterdam, 1681, reprinted with new notes by Van Staveren, Leyden, 1763. There are other works under the name of Hyginus, but they all belong to a later age: *De Limitibus constituendis,* published in a collection entitled *Rei Agrariæ Auctores, cura Goesii,* Amsterdam, 1674; a *Fragment* on the proper mode of pitching a camp, published first by Scriverius, along with Vegetius, Leyden, 1607, and reprinted with a learned commentary by Schelius, Amsterdam, 1661, and also by Grævius in his *Thesaurus.* Angelo Maio, the learned librarian of the Vatican, has added three new works on mythology to those which we already possessed, and one of these is under the name of Hyginus, but evidently by a writer of the fifth century. Other manuscripts of the same works have since been discovered at Göttingen, Gothe, and Paris; and Dr Bode has published a new edition, with a careful collation of these manuscripts, *Scriptores Rerum Mythicarum Latini tres Romæ nuper reperti,* Celle, 1834. For the life of Hyginus, freedman of Augustus, consult Scheffer, *De Hygini Script. Fabul. ætate atque stylo;* and Muncker, *De auctore, stylo, et ætate Mythologiæ quæ C. Hygini nomen præfert.*

HYGROMETRY.

Hygrometry. The formation of steam or aqueous vapour, and its diffusion in space or in a gaseous medium, have already been considered under the article EVAPORATION. We now propose first to take a view of various methods and devices which have been employed to detect the presence of aqueous vapour, and to ascertain its amount, or how much of it is contained in a given volume, whether when alone or diffused in a gaseous medium. This is necessarily connected with, and will in a great measure consist of, the description, theory, and use of such instruments as almost exclusively belong to this branch of inquiry, and which are usually denominated *hygrometers*, from ὑγρος, *moist*, and μετρεω, *I measure.* We shall then consider under what circumstances moisture is deposited from the atmosphere, and shall examine some of the more remarkable phenomena resulting from or connected with the condensation of aqueous vapour.

Two classes of hygrometers. Many contrivances bearing the name of hygrometers have appeared from time to time, and these, though extremely various in their constructions, we shall only divide into two very different classes: 1*st*, Such as are slow or uncertain in their indications, or are formed of decaying or changing materials; 2*d*, such as are not only more prompt in their indications, but are formed of materials comparatively free from change. The former are obviously unfit for hygrometers, but have been so numerous, that a description of the whole of them alone would greatly exceed our limits; which is the less to be regretted, since the greater and more superficial part have already served their day, and gone entirely into disuse. It will, however, be proper briefly to notice a few of those either already become obsolete, or soon to be so, were it only to show their imperfection.

Uncertain and changing class. The earliest account of hygrometers perhaps worth noticing is that contained in the *Philosophical Transactions* for 1676, where several are described, and allusions made to others; but both then, and during more than a century which followed, the indications of such instruments depended on the change which the weights or dimensions of bodies undergo from a change of humidity. Thus, when the weather becomes more damp, the deliquescent salts gradually become heavier from absorbing moisture, and in drier weather lighter from parting with it. The like happens with certain stones and various other minerals; with sulphuric acid and several other liquids; with sponges and many vegetable and animal substances, whose dimensions are considerably though slowly altered by change of humidity. In bodies of a fibrous structure, however, the change of dimension occurs principally in a transverse direction, or across the fibres, and but very slightly in the direction of their length. Thus a beam of straight-grained wood becomes thicker and broader by absorbing moisture, and *vice versa;* while its length is altered in a much smaller râtio. The same thing takes place with whalebone, ivory, and other substances.

Wooden hygrometer. As several sorts of wood are at first very susceptible of participating in the dryness and moisture of the atmosphere, they have sometimes been employed in the construction of hygrometers. For this purpose a small and very thin board is placed on edge, with its ends slightly entering into grooves in two upright pillars, its fibres being in a horizontal direction, so that the expansion or contraction of the board may be vertical; for, as was noticed above, it is principally in the lateral direction, or across the fibres, that wood expands or contracts by change of humidity. On the upper edge of the board is fixed an upright toothed rack, working in the leaves of a small pinion, on whose axis is fixed a wheel, which turns another pinion on the axis of the index. It is thus evident, that a very slight motion communicated to the rack, by the rising or falling of the upper edge of the board, will be greatly magnified by the wheel-work, so as to be shown in a very sensible manner by the index. But the defect of this and all similar contrivances is, that the wood takes such a long while to receive the impressions, whether of humidity or dryness, from the atmosphere, that by the time they indicate greater dampness, the air may have really become drier, and *vice versa;* and besides, the board gradually becomes less sensible to these impressions, till at length the index almost ceases to move.

An obvious consequence of the lateral expansion and contraction of organic fibres is, that ropes, cords, or strings, formed of such fibres twisted together, are rendered thicker and shorter by absorbing moisture, and *vice versa.* On this principle it has frequently been attempted to construct hygrometers, as, for instance, by making fast one end of a piece of rope, cord, or catgut, winding it backwards and forwards over several pulleys, and suspending from its other end a small weight, which, by rising and falling with the alternate shortening and lengthening of the cord, marks, on a graduated scale placed behind it, the changes of humidity. Sometimes the one extremity of the catgut being made fast, the other carries a small weight, and an intermediate part is wound on a small axis, carrying an index round a graduated plate, the degrees of which are meant to mark the humidity or dryness of the air. When a weight is suspended by a fine string, a piece of catgut, or the naturally twisted beard of the wild oat, it will be seen to turn in the one direction or the other, owing to the twisting and untwisting of the cord, from the changes of humidity. The hygrometer or weather-house, commonly sold as a toy, depends on this principle. It usually consists of a kind of box, representing a building with two doors, within which is suspended a horizontal bar, by means of a cord attached to its middle. Upon one end of this bar is a figure of a man, with an umbrella to protect him from the rain, and on the other that of a woman with a fan. They are so adjusted in respect of the doors, that when the man appears it is a sign of rain; but when he withdraws, and the woman presents herself, fair weather is predicted. This contrivance unfortunately has just the same faults as the one first noticed, being both liable to change and decay, so as ultimately to lose almost entirely its sensibility. It is therefore of no other use than as a mere toy; for the value of an instrument employed as a measure of any kind must depend not only on its being at first accurately constructed, but likewise upon its indications not being, *cæteris paribus*, liable to change.

Effects of changes of humidity on cabinet work. The preceding remarks upon the effects of a change of humidity on organic substances may enable us to correct what we consider a great mistake. Slips of metal are sometimes employed to strengthen or bind together cabinet work; and this has been objected to on the professedly scientific ground, that the expansion and contraction of the metal by change of temperature is apt to tear, warp, or distort the wooden work. That some such effects as have just been stated do frequently occur, cannot be denied; but we have no hesitation in ascribing them to a very different and far more powerful cause, the lateral expansion and contraction of the wood itself by changes of humidity, and particularly the permanent contraction due to the gradual loss of natural sap, if the wood has not been

Hygrometry.

previously well seasoned; for the bad effects in question rarely appear at first, and only occur at all when the metal is of considerable length and fixed across the grain of the wood, and more especially when the wood has not been of the proper sort, or has been worked when damp or badly seasoned. Indeed, when a sufficiently strong slip of wood is firmly applied in place of and in the same position as the metal, there is, *cæteris paribus*, no sensible difference in the bad effects; and it is particularly to be remembered, that a rise of temperature which would alter the length of the metal so as to do any harm in the manner supposed, would seriously injure cabinet work although no metal were near it. Wood in general, if exposed to drought, continues to shrink permanently more or less, especially in the lateral direction, or across the fibres, so long as it lasts; and when alternately exposed to the expanding and contracting influences of moisture and drought, the permanent contraction is upon the whole accelerated and increased.

Kater's hygrometer.

The hygrometer invented by the late ingenious Captain Kater depends upon the twining and untwining which the changes of humidity produce in the naturally twisted beard of grass known in the *Canarese* language by the name of *Oobeena Hooloo.* This is the *Andropogon contortum* of Linnæus, and is gathered in the Mysore country in January. The frame of this instrument is commonly cylindrical; and, that it may allow the air to pass freely through, it is formed of small bars of brass, or sometimes of silver. Upon one end of this frame is soldered a flat plate, having a projecting rim, to protect the index which turns upon it over a circular dial divided into a hundred equal parts or degrees. The index, which is very slender and nicely balanced, is put on one end of an axis of silver wire, which has liberty both to turn round and to shift a little longitudinally through double conical holes in the frame. The axis extends about half the length of the frame; and a part of it next the index is formed into a screw of fourteen or fifteen threads. This is effected by twisting tightly round it a smaller silver wire. A loop and drop made of fine gold wire are so formed, that when suspended from the axis, the loop may slide freely along the screw, and by the number of threads thus run over, it can show the number of complete revolutions of the index. The farther end of the axis is swelled a little, and has a notch to receive the end of the *Oobeena Hooloo*, which is fixed by drawing upon it a sliding ring. This beard is then extended in the line of the continuation of the axis, till it meet the frame, where its other end is fixed similarly to the former one, but admits of adjustment by a screw which stretches it slightly. Such is a brief outline of the very simple and ingenious mechanism by which the gradual expansion or contraction of the hygrometric substance communicates a rotatory motion to the index; so that whilst the index shows the fraction of a revolution on the graduated dial, the loop and drop indicate the number of complete revolutions, or the integral number of hundreds of degrees which the index has passed over on the dial. So great is the sensibility of this instrument, that its index makes ten or twelve revolutions, while that of Saussure's only makes one. Captain Kater recommended that all observations made with his hygrometer should be reduced to what they would have been had the entire scale, or the utmost range traversed by the index, consisted of a thousand degrees, which would be ten complete revolutions. By this, we suppose, he meant to render all hygrometers of his construction comparable; a property which, however, belongs to no hygrometers whose principal parts are formed of animal or vegetable substances, which are continually changing, and gradually becoming less and less sensible to the influence of humidity.

Balance hygrometer.

Hygrometers have frequently been formed by suspending from one arm of a balance some substance which strongly attracts moisture from the atmosphere, and nicely counterpoising it by a weight on the other arm. The changes in the humidity of the air are then meant to be indicated by the changes in the position of the beam, arising from the gain or loss of weight in the suspended body. A great variety of substances have been used for this purpose, such as sponge, caustic potash, the deliquescent salts, sulphuric acid, &c. These, like the former instruments, are all too late in their indications, though some of them might scarcely be liable to lose their sensibility, were it not that they soon become useless from the accumulation of dust, soot, &c. especially if in or near a large city.

But the expansions and contractions of hair and of whalebone are, from the tenuity of their substance, somewhat more expeditious in acquiring the humidity or dryness of the surrounding air. They have therefore been employed in the construction of hygrometers; the former by Saussure, and the latter by Deluc. Both these instruments are impaired by time, and they sometimes acquire contrary errors. Their indications generally differ materially, even when graduated alike, and more especially when differently graduated; but so unsteady is the relation between them, even for the same state of the air, that no certain rule can be given for reducing the one to the other. This is evident from the circumstance, that scarcely two authors who do not derive their information from the same source agree respecting the relation between the indications of these instruments. Deluc states, we think, very just objections to Saussure's hygrometer, and as justly does Saussure object to his; so that, had it not been out of respect for the high reputation of these philosophers, and the frequent reference made to their instruments in scientific researches, and in books of voyages and travels, we should scarcely have felt warranted to give even the following brief description of them here. We begin with that of Saussure, which is represented in fig. 3, Plate CCXCV.

Saussure's hygrometer.

The lower end of the hair *ab* is held by the screw-pincers *b* at the bottom of the frame. These pincers, shown separately at B, fig. 4, terminate in a screw which enters the hollow screw C, fig. 5. By turning this screw, the pincers *b* or B may be raised or lowered at pleasure. The other end *a* of the hair is held by the inferior mouth of the double and moveable pincers *a*, seen separately at A, fig. 6, and which, with their upper mouth, take hold of a fine well-tempered silver wire, which is wound round the arbor *d*. This arbor, seen separately at DF, fig. 6, carries the index *ee*, marked E in the separate figure 6, and is cut like a screw, with a flat-bottomed groove to receive the silver wire, which, as mentioned above, is connected with the hair by means of the double pincers. The wire was adopted from its being found that, when the hair itself was wound on the arbor, it became rough, and contracted a stiffness, which the small weight *g* or G, employed as a counterpoise, could not overcome; whereas a proper wire always preserves the same flexibility. It was necessary thus to cut the arbor like a screw, that the wire might not have its coils wound one upon another, so as to thicken the arbor, or to take a position too oblique and uncertain. The wire is fixed to the arbor by a small pin F. The other end D of the arbor has the form of a pulley, with a groove flat at the bottom to receive a fine silk thread, by which is suspended the counterpoise marked *g* in fig. 3, and G in fig. 6. This is intended to keep the hair always gently stretched. One end of the arbor, formed into a fine pivot, passes through the centre of the dial, and carries the index *ee* on its extremity. The other end has a similar pivot turning in the arm *h* of the doubly-kneed piece *hi*, or HI, fig. 7, which is fixed to the back of the dial *kk* by the screw I. The dial is divided into 360 degrees, and is soldered to two tubes *ll*, which surround and can be slid up and down the two upright wires *mm, mm* of the frame. The dial can thus be fixed at any place on the wires by means of the screws *nn*. The square column *pp* carries a box *q*, to which is fixed a sort of pencil-case *r*, fitted to receive the counterpoise *g*. When the hygrometer is to be transported to another place, and some harm is apprehended from the vibrations of the counterpoise, the case *r* is raised to receive it. Both are then made fast by the screws *s* and *t*. When, again, the hygrometer is to be used, the counterpoise is disengaged, and the box lowered as in the figure. At the corners of the base of the frame are four screws *o, o, o, o*, for the purpose of levelling the base, or making the instrument stand upright. The three columns of the frame are connected at the top by the crooked piece *xyx*, having a hole at *y*, by which the instrument may be suspended.

The point of extreme dryness is obtained by placing the instrument under a receiver, with a quantity of quicklime or caustic alkali; and that of extreme moisture by enclosing it in a receiver whose sides are kept continually moistened. This last Deluc regards as very fallacious.

The scale of Saussure's hygrometer sometimes contains 100 divisions or degrees, and sometimes a larger number. That in our figure has 360. Saussure gives a decided preference to human hair, which he first causes to undergo a preparation, for the purpose of divesting it of a kind of natural oiliness, which, if not removed, would render it less sensible to the action of humidity. This preparation is made at the same time on a considerable number of hairs forming a tuft, the thickness of which need not exceed that of a quill. This tuft being enveloped in a bit of fine cloth, as in a case, is immersed in a long-necked phial full of water, holding in solution about the hundredth part of its weight of sulphate of soda, and which is made to boil about three minutes. The tuft is then passed through two vessels of pure water at the boiling temperature; afterwards the hairs are drawn from their wrapper and separated; then they are hung up to dry. It only remains to select those which are cleanest, softest, most brilliant, and most transparent. The effects of dryness and of moisture upon the hair are modified by those of heat, which affect it in different ways. Thus, if it be supposed, for example, that the air becomes warmer about the hygrometer, its drying quality being thereby increased, it will abstract from the hair a part of the water which it had imbibed, thus tending to shorten it; while, on the other hand, the heat, by expanding the hair, will tend, though in a much smaller degree, to lengthen it; so that the total effect will consist of the excess of the former over the latter. It is therefore necessary, where precision is aimed at, to consult the thermometer, and apply a corresponding correction.

Properties of perfect hygrometer.

In his *Essais sur l'Hygrométrie*, M. de Saussure, while he candidly acknowledges the imperfection of his own instrument, enumerates the following as properties which he thinks a perfect hygrometer ought to possess: 1*st*, Its variations should be sufficiently extensive to show very small changes of humidity or dryness; 2*d*, these indications should be so prompt as to proceed *pari passu* with the actual state of the air; 3*d*, the instrument should always accord with itself; that is to say, in the same state of the air it should always be found at the same degree; 4*th*, it should be comparable; that is to say, any number of hygrometers constructed separately upon the same principles should always indicate the same degree in the same circumstances; 5*th*, it should only be affected by humidity or dryness properly so called; 6*th*, the variations in the indications should be proportional to those of the air; so that, in like circumstances, a double or triple number of degrees should always indicate a double or triple quantity of moisture.

This last property, however, we cannot regard as by any means indispensable to a perfect hygrometer, though we grant that an instrument possessing it is likely to be somewhat more convenient. For it is quite clear, that if we only knew the true relation between the indications of the instrument and the state of the air, we could by that means compute the degree of humidity with perfect certainty; no matter how much the variations of the indications of the instrument and those of humidity differed from simple proportionality.

Deluc's hygrometer.

We shall next give a brief description of Deluc's hygrometer. The frame will be readily understood from inspecting fig. 1, Plate CCXCV. The principal part consists of a slip of whalebone, cut transversely, or across the fibres, and is represented by *ab*. Its end *a* is held by a very simple sort of pincers, made of a bit of flattened wire bent and pressed together on the whalebone by a sliding ring. The other end *b* is fixed to a bar *c*, which can be moved by a screw for adjusting the index *e*, to have a proper position at first on the dial. The loop of the pincers which hold the whalebone is hooked to the end of a thin brass wire, to the other end of which is also hooked a very thin silver gilt lamina, which has at that extremity pincers similar to those of the whalebone; but its other extremity is pinned into a hole in the axis. The spring *d* which stretches the whalebone is made of silver gilt wire; it exerts a force equal to a weight of twelve grains, but with this among other advantages over a weight, that in proportion as the slip is weakened by lengthening, the spring relaxes its force by unbending. The axis has very small pivots, whose ends are confined, to prevent the shoulders from rubbing against the frame. A section of this axis is shown on a large scale in fig. 2. The slip acts on the diameter *aa*, and the spring on the smaller diameter *bb*. The point of extreme dryness is obtained by enclosing the instrument under a receiver, along with some quicklime; that of extreme humidity, by wetting the whalebone with water, or immersing the whole instrument in it. The graduated arc on the dial is about five sixths of the entire circle, and is divided into 100 equal parts or degrees. The zero denotes extreme dryness, and the 100th degree extreme humidity. Saussure, however, alleges that the whalebone is more thoroughly soaked or swelled by immersion in water than in the most humid air, which, he says, never brings it to the extremity of the scale.

Deluc maintains that hairs and other animal or vegetable hygroscopic substances taken lengthwise, or in the direction of their fibres, undergo contrary changes from different variations of humidity; that when immersed in water, they lengthen first, and then shorten; that when they are near the extreme of humidity, they shorten with an increase and lengthen with a diminution of humidity. This he regards as the necessary consequence of their organic reticular structure; and in illustration of it he has given the following comparison between the corresponding indications of his own hygrometer and those of Saussure. The scale of each is supposed to be divided into 100 degrees.

Deluc.	Saussure.	Deluc.	Saussure.
5	15·6	55	88·8
10	29·4	60	91·6
15	40·9	65	93·8
20	50·5	70	95·6
25	59·2	75	97·2
30	68·8	80	98·0
35	73·0	85	100
40	78·3	90	100
45	82·1	95	99·3
50	86·1	100	98·3

 P

From this it would appear, that after the hair becomes very moist, its lateral expansion produces a contraction in the length, as in the case of ropes. Saussure, however, alleges that in this trial his instrument must have been in bad order; and he even retaliates by ascribing as great defects to that of Deluc. According to Boeckman, 10, 20, 30, 40, 45 of Deluc correspond to 33, 54, 65, 80, 86 respectively of Saussure; but in atmospherical observations he found Deluc's at 56 and 48, when Saussure's indicated 85 and 90 respectively.

M. Gay-Lussac has made many experiments on the hair hygrometer, which would place it in a rather more favourable light than the above; and M. Biot has exerted his great analytical skill in endeavouring to perfect its theory, by giving, in his *Traité de Physique* (tome ii. p. 199), a very elaborate investigation of the relation between its indications and the actual humidity, which has been farther illustrated at great length by Signor Melloni, in the *Annales de Chimie et de Physique* for January 1830. But unfortunately this relation is so soon deranged by the rapidly changing and perishable nature of the instrument, as to render all such labours of very little use, no matter how much learning or ingenuity may have been expended on them.

It will be unnecessary here to notice Deluc's ivory hygrometer, because a description of an improved instrument of the same kind will be found under the article METEOROLOGY.

Wilson's hygrometer.

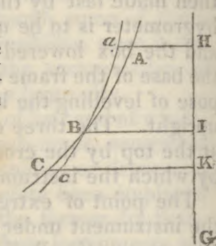
Mr Wilson's hygrometer is very similar to a mercurial thermometer; but in place of the bulb being of glass, it consists of a rat's bladder, which when new is very sensible to changes of humidity; so that by expanding with moisture, or contracting with drought, it produces corresponding depressions, or rises in the column of mercury in the glass stem. This instrument must obviously have its indications somewhat affected by changes of temperature like a thermometer; and, in addition to some of the imperfections common to the instruments already described, it has been objected that the pressure of the column of mercury in the stem must occasion a variable, and perhaps increasing distension of the bladder.

Relations of air to heat.

The foregoing we presume to be sufficient specimens of such hygrometers as are slow or uncertain in their indications, or formed of comparatively changing and perishable materials. These, too, we should think, have been treated at as great length as the little and decreasing importance now attached to them seems to warrant. But since the science of heat lies at the foundation of all accurate knowledge in hygrometry, we now propose, preparatory to entering on the consideration of such hygrometers as are more durable in their construction and constant in their indications, to investigate some relations of air to heat, which will be useful in the sequel of this article. In so doing we shall reason from admitted principles only; for we see no necessity for calling in the aid of the old notion which some are so anxious to revive again, that heat is a species of motion; because such a hypothesis, in place of solving the difficulties, is, like "the occult qualities," a mere subterfuge for our ignorance, or an excuse for not encountering the difficulties, and unavoidably leads to still greater difficulties; whereas the more closely the other theory is traced, the more the difficulties, numerous as they still are, disappear. Of this we shall have occasion to notice several instances in the course of this research. We now begin the investigation with a brief demonstration of the following preliminary proposition.

Lemma.—If the area of a curve between every two ordinates be such that, when cut by a third ordinate in a given ratio, the two corresponding differences in the logarithms of the three abscissæ are likewise in that ratio, the curve is a hyperbola.

Let the curve ABC be such, that when AHKC, its area between any two ordinates AH, CK, is cut by any third ordinate BI, making area AHKC to AHIB in the given ratio of m to n, the three corresponding abscissæ reckoned on the straight line GH from a fixed point G, are related thus; log. GK — log. GH : log. GI — log. GH : : m : n, the curve ABC is a hyperbola.



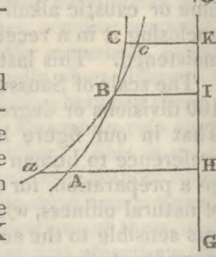
For if not, with G as a centre, GH as one asymptote and the other parallel to AH, describe through B the hyperbola aBc cutting AH and CK in a and c. Then by the well-known property of the hyperbola,

area $aHKc$: $aHIB$: : log. GK — log. GH : log. GI — log. GH.

But AHKC : AHIB : : log. GK — log. GH : log. GI — log. GH;

wherefore, by equality of ratios, alternation and division,

BIKC : BIKc : : AHIB : aHIB.



If cK $<$ CK, and aH $>$ AH, and if the curves do not again meet between A and C, the first term of the analogy last stated must exceed the second, while yet the third is less than the fourth, which is absurd. The like would as readily follow, were cK $>$ CK and aH $<$ AH.

But it is evident that in every case in which the hyperbola is supposed to cut the other curve, the same process of reasoning will lead to the like absurdity, if three ordinates intercepting areas in the given ratio be drawn so close together as to embrace no other meeting of the curves but the foresaid intersection. Now such a construction is always practicable; for in every case two of three such ordinates may be drawn arbitrarily, viz. one through the point of intersection, and a second as close as we please to either side of it; whilst the abscissa which gives the position of a third still nearer, if wished, on the other side, may be had from such an analogy as was stated above, namely,

log. GK — log. GH : log. GI — log. GH : : m : n.

It is indeed a supposable case, that the hyperbola, in place of cutting, might have the other curve wholly on one side, only touching it in the point B; but then it is evident that another hyperbola drawn near enough to that side of the former one, and having the same asymptotes, could not fail to cut the curve ABC. Of course, three ordinates being drawn as before, viz. one through the point of intersection, and the other two near enough to it, would still produce the former absurdity. Hence the curve ABC can only be a hyperbola.

The physical principles which we are about to employ as data for investigating the relations of air to heat, are essentially the same as those from which MM. de Laplace and Poisson attempted to deduce the true scale of the air-thermometer, as may be seen in the *Mécanique Céleste* (tome v. p. 127), and *Annales de Chimie et de Physique* (tome xxiii. p. 337); where, after proceeding so far, and with data which, if properly managed, were amply sufficient for their purpose, they abandoned the project, and contented themselves with *assuming* that the common mode of graduating an air-thermometer forms a true scale of temperature. This they were forced to do in consequence of having adopted a mode of investigation so unnecessarily abstruse that it soon became quite unmanageable. That they should have failed to *prove* the common scale to be the true one, need excite no surprise; for we shall soon see that such a result would be quite incompatible with the very principles from which they attempted to deduce it, and that, without the aid of any assumption, a much more simple process of reasoning, illustrated by a diagram or two, would have necessarily led them to the legitimate, though a very different, result. These principles or data, and some inferences from them, we shall now distinctly state, numbering a few of the paragraphs as we proceed, chiefly for the sake of after reference, and not as if we were specifying so many independent data: for the whole force of the reasoning rests on the first two; the third is merely an inference from the second; and the only use here made of the fourth and fifth is to trace more readily, in known terms, the relation between the common scale of the air-thermometer and the results to which this investigation leads.

1. The law of Boyle and Mariotte, that at the same temperature the elasticity or pressure of air is as its density, or inversely as its volume; and consequently, while air undergoes the same change of temperature, its volume varies under a constant pressure, precisely in the same proportion as the pressure would do were the air confined in an inextensible vessel.

2. If s denote the specific heat of air when it sustains a constant pressure, and s' the specific heat of the same mass of air when confined in an inextensible vessel; then it has been ascertained, through a great range of temperature and pressure, as will be afterwards explained, that s always exceeds s' in a constant ratio, which we may now call the ratio of m to n, which are constants; but their values not being now given, will show our investigation to be independent of the value of their ratio.

These two, viz. the law of Boyle and the *constancy* in the ratio of m to n, are the principles to which we have alluded above as being employed by MM. de Laplace and Poisson, and as being quite sufficient, if properly managed, to have unavoidably led these great mathematicians to the conclusion that air expands in geometrical progression for equal increments of heat. But this, and most of the other legitimate results, they failed to reach, in consequence of unnecessary intricacy, and their introducing an assumption which we shall shortly see to be quite incompatible with the data now specified. The second principle, as will be afterwards noticed more particularly, was first shown by the illustrious M. de Laplace himself to be a necessary deduction from the fact ascertained by the experiments of MM. Desormes and Clement, and more especially by those of MM. Gay-Lussac and Welter, which were continued through a great range of temperature and pressure, viz. that when the density of air suffers a minute and sudden change, m times such variation of density is to the whole density as n times the accompanying variation of pressure to the whole pressure. Or, ϱ being the density and p the pressure,

$$m d\varrho : \varrho :: n dp : p \text{ ; and } \frac{n dp}{p} = \frac{m d\varrho}{\varrho}.$$

3. The last equation evidently expresses the relation between the fluxions of the logarithms of the pressure and density of air when the total heat in it is constant. The fluent is $n \log. p = m \log. \varrho + C$; so that if p' and ϱ' be put for the initial values of p and ϱ, we have $C = n \log. p' - m \log. \varrho'$, and

$$n \log. \frac{p}{p'} = m \log. \frac{\varrho}{\varrho'} \text{ ; or } \left(\frac{p}{p'}\right)^n = \left(\frac{\varrho}{\varrho'}\right)^m,$$

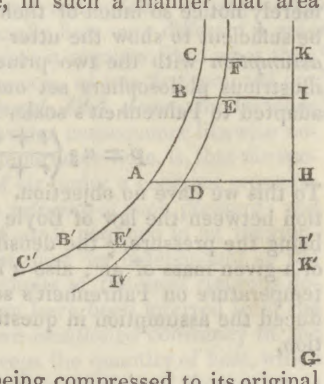
which is the relation between the pressure and density of air, when the total heat in it is invariable.

4. It has been ascertained by Dr Dalton, M. Gay-Lussac, &c. that on heating air under a constant pressure from 32° F. to 212°, its bulk acquires an increase of three eighths. Such increase, in the common graduation of the air-thermometer, is divided into 180 equal parts or degrees for Fahrenheit's scale; and the like divisions corresponding to equal variations of bulk, are continued both above 212° and below 32°, viz. upward indefinitely, but downward they have a limit; for as three eighths are to 180°, so is the whole bulk at the freezing point to 480°; and therefore more than 480 degrees cannot with propriety be reckoned or put below 32° on the Fahrenheit scale of an air-thermometer.

5. Since the freezing point is marked 32°, it is obvious that 480 degrees will reach from it down to $-448°$. The bulk of a given mass of air, therefore, under a constant pressure, varies as its temperature reckoned from $-448°$ on the common scale; that is, as $t + 448$, the degrees of Fahrenheit being t. Hence, by art. 1, the pressure of air confined in an inextensible vessel, likewise varies as $t + 448$.

Relation between the variations of heat in air and those of its volume or pressure.

We shall now apply these principles to determine the scale of temperature for air. Let ABC be a curve, such that, while AHIB, its area between any two ordinates, denotes an addition to the heat contained in a given mass of air, the straight line HI shows on the common scale the consequent rise of temperature, under a constant pressure, viz. from H to I, as indicated on the common scale of an air thermometer. Let DEF be a similar curve, making AH : DH :: m : n, and cutting all the other ordinates and areas of ABC in that same ratio. Hence, area DHIE is equal to $\frac{n}{m}$ (AHIB), and it therefore (art. 2) represents the smaller addition of heat which would be sufficient to raise the temperature of the same air from H to I, were that air, in place of being free to expand under a constant pressure, confined in an inextensible vessel. For since the specific heats or the minute increments are always in the ratio of m to n, so must any larger addition of heat raising the temperature from H to I under a constant pressure, be to that producing the same rise under a constant volume. Let the common scale, of which HI is a part, be continued downward to the point G answering to $-448°$ Fahrenheit; then (art. 5) the volume of the air is increased, under a constant pressure, in the ratio of GI to GH, by its temperature being raised from H to I. Suppose, therefore, that the air, after having, under a constant pressure, received an increase in its total heat equal to AHIB, and thereby acquired the temperature I, is instantly compressed to its original volume; by which means its temperature is suddenly raised from I to K on the common scale, in such a manner that area DHKF = AHIB; because the air is evidently now raised to the same temperature, and in every respect brought to the same state as if, with its original volume all the while invariable, it had received the same increase in its quantity of heat as is mentioned above, and which is now denoted by area DHKF instead of AHIB.



While the air was thus being compressed to its original volume, or the density re-increased in the ratio of GI to GH, the pressure has been thereby increased (art. 1) in the same ratio compounded (art. 5) with the ratio of GK to GI for the second rise of temperature; that is, in the ratio of GK to GH; and during this compression the total quantity of heat in the air is supposed to be constant. Hence,

$$\text{(art. 3)} \; \frac{GK}{GH} = \frac{p}{p'} ; \; \frac{GI}{GH} \frac{\varrho}{\varrho'} \text{ ; } n \log. \frac{GK}{GH} = m \log. \frac{GI}{GH},$$

and therefore log. GK — log. GH : log. GI — log. GH :: $m : n$. But we have also area AHKC : AHIB :: $m : n$, because AHIB = DHKF; and the same thing holds at any part of the curves. Consequently, by the lemma, each of these curves is a hyperbola, having G for its centre and GH for an asymptote.

All the preceding reasoning evidently applies as well to the accented letters in the lower part of the figure, where AHI′B′, the area between any two ordinates, denotes a loss of heat, HI′ the consequent depression of temperature on the common scale in cooling from H to I′ under a constant pressure, and I′K′ a farther depression, such that area DHK′F′ = AHI′B′; being caused by suddenly dilating, to its original volume, the air which had just been contracted by cooling from H to I′.

Relation between the variations of heat in air and those of its volume or pressure.

Since in each curve the segments of the area denote variations of heat, while the corresponding segments of the abscissæ denote variations of temperature on the common scale, it follows from the known property of the hyperbola, that while the variations of the quantity of heat in air under a constant pressure are uniform, those on the common scale of an air-thermometer form a geometrical progression. Or, in more general terms, while the variations in the quantity of heat in air are uniform, the variations of its volume, under a constant pressure, form a geometrical progression, as do likewise the variations of pressure under a constant volume.

Hence, in place of being equal, the divisions on a true scale of an air-thermometer should form a geometrical progression, increasing upward, such that the length of each division may be proportional to its distance from — 448° F.; and hence also the values of the degrees usually put on Fahrenheit's scale of an air-thermometer decrease upward, the value of each being inversely as its distance from — 448°. The same thing holds regarding any other scale with equal divisions.

Such are some of the necessary results of the very principles from which MM. de Laplace and Poisson failed to deduce a corresponding scale of temperature; we mean a scale which should necessarily follow from, and be compatible with, the law of Boyle and the foresaid *constancy* in the ratio of m to n. But having failed in this, they attempted to supply the defect, by *assuming* that the variations in the quantity of heat in air, under a constant pressure, are proportional to the corresponding variations on the common scale of an air-thermometer. We shall merely notice so much of their investigation here as will be sufficient to show the utter incompatibility of such an *assumption* with the two principles just named. These illustrious philosophers set out with an equation which, adapted to Fahrenheit's scale, is

$$p = a\varrho\left(\frac{t + 448}{\tau + 448}\right).$$

To this we have no objection. It just expresses the relation between the law of Boyle and the common scale; p being the pressure, ϱ the density, and t the temperature, of a given mass of air; also a is a constant and τ a given temperature on Fahrenheit's scale. Having next introduced the assumption in question, they obtain the equation,

$$q = \mathrm{A} + \mathrm{B}\,(t + 448)\,p^{\frac{-m}{m}},$$

where q is the quantity of heat to be added or withdrawn, in order to change the temperature of the given mass of air from τ to t; A and B are constants, and m and n numbers in the constant ratio already defined. By combining the two equations, we have likewise

$$q = \mathrm{A} + \frac{\mathrm{B}\,(\tau + 448)\,p^{\frac{n}{m}}}{a\varrho}$$

Taking the fluxion of this with the density ϱ constant, we have dq varying, as $p^{\frac{n}{m}-1}\,dp$. But the constancy in the ratio of m to n provides that the change to be made in the quantity of heat in air, in order to produce a given change in its temperature, under a constant pressure, must be proportional to the change of heat necessary to produce the same change of temperature, were the volume constant; and it is well known to be the same thing, whether variations of temperature on the common scale are reckoned by the variations of volume under a constant pressure, or by variations of pressure under a constant volume. Hence Laplace and Poisson assume the variations in the quantity of heat to be proportional, as well to the variations of pressure under a constant volume, as to the variations of volume under a constant pressure. Wherefore dq varies as dp simply; but we have just seen that it likewise varies as $p^{\frac{n}{m}-1}\,dp$. Consequently $p^{\frac{n}{m}-1}\,dp$ varies as dp; and dividing by dp, we have $p^{\frac{n}{m}-1}$ varying as a constant quantity, which is extremely absurd. Yet the very same data and assumption which give rise to this contradiction, form the foundation of many intricate formulæ in the *Mécanique Céleste*, and of a very long memoir on heat by M. Poisson, in the eighth volume of the *Mémoires de l'Académie*.

From the remarkable inconsistency just pointed out in the principles adopted by these illustrious philosophers, it is evident that they had not had so much as a conjecture of what the legitimate result should be. Nobody wonders when a research of this sort fails in the hands of an inexperienced tyro; but if those who are deservedly regarded as at the head of their profession be liable to deceive themselves in so remarkable a manner, how cautious ought we to be in receiving even what emanates from high authority, if accompanied by nothing deserving the name of argument or intelligible evidence; for the foregoing investigation, we presume, will be found to be both legitimate, and to depend on nothing but admitted principles. It is long since our distinguished countryman, Dr Dalton, proposed what he alleged to be the true scale of the mercurial thermometer, founded on the supposition that the expansions of liquids were everywhere as the squares of their true temperatures, setting out from the greatest density of each. With this he coupled another speculation: he supposed that, relatively to equal intervals on his new scale of temperature, the expansions of air, or of any other gas, under a constant pressure, formed a geometrical progression; which evidently was a very different scale from the one we have deduced above, because, as will presently be seen, it bore such a different relation to the expansion of mercury. For, unfortunately, these views, which Dr Dalton had never shown to be necessarily deducible from admitted principles, were soon found to be mutually incompatible; but of the two hypotheses, that regarding the expansion of mercury being the greater favourite with Dr Dalton, he rather chose to retain it, and abandon the one respecting the expansion of air; in place of which, he has since, in his *Chemical Philosophy* (vol. ii. p. 298, published in 1827), adopted the very different notion, that it is the forces of steam, and of other vapours in the state of saturation, which form geometrical progressions for equal intervals of temperature. It was absolutely necessary that the one of his former hypotheses should be relinquished; for they were not only inconsistent at extreme temperatures, but they required the common mercurial thermometer to be more than 7° below the common air-thermometer at 122° F.; whereas at that point, several eminent French chemists declared they could find no such difference; and in their decision Dr Dalton at length acquiesced.

Hy ome- y.

However, from the recent comparison of these two instruments by Dr Prout, it appears that their indications do not everywhere coincide throughout the interval between the freezing and boiling points of water; but their difference is quite of the contrary sort to that which Dr Dalton alleged, the mercurial thermometer being in advance of the other.

It was shown (art. 3) that $\left(\frac{p}{p'}\right)^n = \left(\frac{\varrho}{\varrho'}\right)^m$; viz. that when the total quantity of heat in a given mass of air is constant, the *n*th power of the pressure varies as the *m*th power of the density; and since *m* is greater than *n*, the pressure varies faster than the density, or $\frac{p}{p'} = \left(\frac{\varrho}{\varrho'}\right)^{\frac{m}{n}}$. But in this, a part of the variation of pressure is due to change of temperature; for (art. 1) when the temperature is the same, the pressure and density vary in the same ratio. Also (by art. 1 and 5), when along with a change of density from ϱ' to ϱ, the temperature changes from τ to t, and the pressure from p' to p, they are related thus; $\frac{p}{p'} = \frac{\varrho}{\varrho'} \times \frac{t+448}{\tau+448}$; and if during this the total heat in the air undergo no change, this equation must coincide with the preceding one. Hence

Cl ge of te era- tu by co non sc due to ange of lume.

$$\frac{t+448}{\tau+448} = \left(\frac{\varrho}{\varrho'}\right)^{\frac{m-n}{n}} = \left(\frac{p}{p'}\right)^{\frac{m-n}{m}};$$

and therefore, on the common scale, the change of temperature is

$$t - \tau = (\tau + 448)\left[\left(\frac{\varrho}{\varrho'}\right)^{\frac{m-n}{n}} - 1\right]$$

$$= (\tau + 448)\left[\left(\frac{p}{p'}\right)^{\frac{m-n}{m}} - 1\right],$$

when the total quantity of heat in the air is constant. This investigation is given in general terms, but we shall soon see that *m* is to *n* either exactly or very nearly as 4 to 3; and therefore,

$$\frac{m-n}{n} = \tfrac{1}{3}, \qquad \frac{m-n}{m} = \tfrac{1}{4}.$$

Most of the formulæ which have been proposed for this purpose are fraught with inconsistencies, such as making the rise of temperature which would be produced by a quadruple compression, to be very different from the sum of the separate rises which should be produced by twice doubling the density; and they are equally faulty when we compare a quadruple dilatation with twice halving the density. Nay, when we attempt to retrace our steps by reversing either process, they do not restore the air to the same temperature and pressure which it had at first; but the formulæ now given, unless when sadly mismanaged, lead to no such inconsistencies. Thus, suppose the density of air at the temperature of 60° to be quadrupled, the rise of temperature is $(60 + 448)\left[\left(\frac{4}{1}\right)^{\frac{1}{3}} - 1\right] = 298°·4$. To effect the same thing by two separate doublings, we have first $508\,[2^{\frac{1}{3}} - 1] = 132°·04$, which, added to the initial temperature 60°, makes 192°·04; and by doubling again the density of the air at this higher temperature, the second rise is $(192·04 + 448)\,[2^{\frac{1}{3}} - 1] = 166°·36$. So that the total rise is 132·04 + 166·36 = 298°·4, the same as before. The like consistency will be found to hold with any proper trial of these formulæ. (See *Edinburgh Phil. Journ.* for July 1827, p. 153.)

Hygrometry.

Quantity of heat evolved or absorbed by change of volume.

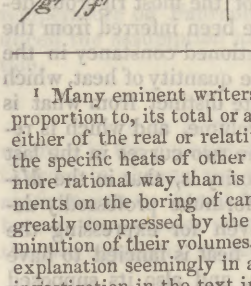
From the foregoing investigation it is likewise evident, that if the total heat in a given mass of air undergo no change, while its density is being increased in any assigned ratio, as, for instance, in the ratio of GI to GH (see the preceding figure), the temperature is thereby raised from I to K on the common scale, making area DHKF = AHIB. In this case the area EIKF = ADEB represents the heat which has been elicited from a latent state, or rendered sensible by the compression. But if, on the contrary, the density of the air were diminished in the ratio of GI′ to GH, without any change in the quantity of heat, the temperature would be thereby lowered from I′ to K′, making area DHK′F′ = AHI′B′; and area E′I′K′F′ = ADE′B′ would denote the heat absorbed by the dilatation, or rendered latent without being actually lost. Now, area EIKF $= \frac{m-n}{n}$ (DHIE) $= \frac{m-n}{m}$ (DHKF), and E′I′K′F′ $= \frac{m-n}{n}$ (DHI′E′) $= \frac{m-n}{m}$(DHK′F′); wherefore area EIKF, or the heat evolved by compression, bears the same ratio to DHIE that the $\frac{m-n}{n}$ part of the increase in the logarithm of the density bears to log. GI — log. GH; and the same is also the ratio which area E′I′K′F′, or the heat absorbed by the dilatation, bears to DHI′E′, or which the $\frac{m-n}{n}$ part of the decrease in the logarithm of the density bears to log. GI′ — log. GH. In both cases, the $\frac{m-n}{n}$ part, or one third of the change in the logarithm of the density, is equal to the $\frac{m-n}{m}$ part, or one fourth of the change in the logarithm of the pressure; the total heat remaining invariable. It matters not what sort of logarithms are used.

Specific heat of air independent of the magnitude of its volume if constant, and of the intensity of its pressure if constant.

Although the *constancy* in the ratio of the specific heats, or of *m* to *n*, as already defined, had been well ascertained by the experiments of Gay-Lussac and Welter, and been likewise adopted as a fundamental principle by the leading philosophers both here and on the Continent; yet the most important of its necessary and unavoidable consequences were long overlooked, especially how very different a graduation of the air-thermometer it requires from what they had assumed to be the true one, as was first pointed out by Mr Meikle in the *Edinburgh Phil. Journ.* for October 1826, page 336. A more obvious consequence likewise noticed in that paper, and of importance here, is, that the specific heat of the same mass of air under a constant pressure, must be independent of the *intensity* of such pressure; and that when the same mass of air is confined in an inextensible vessel, its specific heat must be independent of the *size* of that vessel. This admits of the most rigorous demonstration, and might even have been inferred from the consideration that the above-mentioned constancy in the ratio of the specific heats keeps the quantity of heat, which merely raises the temperature quite distinct from what is absorbed, or goes to enlarge the volume, and which is represented by the area between the two curves in the last figure. Now the remarkable curiosity is, that in the *Mécanique Céleste*, livre xii. chap. 3, formulæ professedly derived from the same data are given for expressing the *different* values which the specific heat is fancied to have under different constant pressures, and also its supposed *different* values under different constant volumes. The same are given by M. Poisson (*Annales de Chimie*, xxiii. 338).

M. Laplace had previously given in that journal (xviii. 185) a very different, though still a *variable* value to the specific heat of air; but this he virtually discarded, by subsequently adopting the other, though both are alike incompatible with the principles from which they profess to be deduced. Sanctioned by such names, these formulæ are and must be received as orthodox by those who never think for themselves, or who do not thoroughly examine the investigations by which such expressions are deduced. But since the clearing up of this point is of great importance in researches of this nature, we shall endeavour to put the matter beyond dispute, by giving, from the very data used by Laplace and Poisson, a very simple demonstration of what we have now alleged, and which is the more satisfactory as it does not require the law of temperature to be previously decided upon; for since the same degree may be used for the several specific heats, it may be supposed to belong to any scale.

Let therefore the temperature of a given mass of air be reckoned on any scale of which the straight line BE is a part; and let CF be a line, no matter to our present purpose whether straight or curved, if it be such that every two ordinates may, like BC and EF, intercept an area BCFE proportional to the quantity of heat which would raise the temperature of the mass of air, under a constant volume, from any point B in the scale to any other point E in it. Let DG be a similar line or curve, so as to make the area BDGE proportional to the heat which would raise the temperature of the same mass, if under a constant pressure, from B to E. Now the chief condition on which we proceed is, that the quantities of heat represented by every two areas, such as BDGE and BCFE, between the same parallels, may be to each other in the given ratio of m to n, and which is obviously the same with the ratio of any ordinate of DG to the corresponding ordinate of CF. Let the point B mark the initial temperature, whatever that may be, of the given mass of air; raise this temperature from B to any other point E under a constant pressure; make Ee one degree, draw the ordinate efg. Then area EGge is the specific heat, at the temperature E, of the same mass of air dilated by heat under the original pressure remaining constant. Now the specific heat, when the pressure is constant, is always to the specific heat when the volume is constant as m to n; but area EGge : EFfe : : m : n; wherefore EFfe would be the specific heat at the temperature E, under the dilated volume, were it made constant. But since area BCFE is the quantity of heat which would raise the temperature from B to E under the original volume, and area EFfe the heat which would raise it one degree more; therefore EFfe would still have been the specific heat of the same mass of air at the temperature E, and all the while under the original volume. Hence EFfe is the specific heat of the same mass of air at the temperature E, whether under the *dilated* volume remaining constant, or under the *original* volume constant.



Again, suppose the air to be heated up from B to E under the original volume remaining constant, by which means the pressure will be gradually augmented; but by the data, the specific heat at the temperature E, under the augmented pressure, were that now made constant, must exceed EFfe in the ratio of m to n; wherefore EGge, which exceeds EFfe in that ratio, is the specific heat of the same mass of air at the temperature E, whether under the *augmented* pressure remaining constant, or, as in the first case above mentioned, under the *original* pressure constant. The same conclusions would obviously follow by a similar process of reasoning, taking the second temperature at any point E′ lower than B. Both cases might also be proved in several ways, a little differently from the preceding; as, for instance, by showing that EFfe or E′F′$f'e'$ will be the specific heat of the same mass of air under a constant volume, as well after the temperature has been changed from B to E or E′ by a change in the quantity of heat only, as by a change in the volume only; and of course EGge or E′G′$g'e'$ will be the corresponding specific heat under a constant pressure, whether under the original pressure constant, or under the pressure made constant after being thus changed.

It is thus clearly established as a necessary result of admitting the *constancy* of the ratio above mentioned, that neither the *magnitude* of a constant volume, nor the *intensity* of a constant pressure, has any thing to do with the specific heat of a given *mass* of air.[1] From this it is obvious that the specific heat of a given *volume* of air is, *cæteris paribus*, as its mass or density.

The experiments of Desormes and Clement on the specific heats of gases (*Journal de Physique* for December 1819), have been supposed to make the specific heat of a given volume of air to vary as the square root of its density; but we do not see how they warrant any thing of the sort. These distinguished chemists having enclosed air in a glass globe, placed it in an empty trough, which they next filled up with hot water, and assumed that the specific heat of the air was exactly proportional to the time which it and the globe took to acquire the same temperature with the water; whereas, for aught that is known to the contrary, the specific heat of the air might follow some other power or root, or some very complex function of the time. Nor do they make any allowance for the share which the mass or matter of this globe, which far exceeded that of the included air, had in protracting the time; or for the different mobilities, and consequently different conducting powers, of different gases, or of the same gas at different pressures. Thus, when the globe was filled with hydrogen, it was probably from the extreme mobility and great conducting power of that gas that the time of its attaining the temperature of the hot water was scarcely two thirds of that in the case of air; and it is as natural to think, that when filled with carbonic acid, it was the more sluggish motions of that gas which rendered the time one half longer than in the case of air; for the experiments of Dr Haycraft

---

[1] Many eminent writers, without any evidence, take it for granted that the specific heat of a body depends on, or is in exact proportion to, its total or absolute heat; which is the more remarkable, considering that nothing is yet known, or likely ever to be, either of the real or relative values of the absolute heats of different bodies. But if we suppose, with far greater probability, that the specific heats of other bodies, as well as that of air, have no dependence on their volumes, this would enable us to account, in a more rational way than is usually done, for the heat accompanying friction, as, for instance, in Count Rumford's well-known experiments on the boring of cannon. Thus the grains of metal worn off by the intentionally blunt borer used on that occasion would be greatly compressed by the abrasion, and so might emit much heat without having their specific heats in the least impaired by the diminution of their volumes. In this way too the evolution of heat would continue as long as the wear and friction; which affords an explanation seemingly in accordance with the fact, without having recourse to the old notion that heat is a species of motion. The investigation in the text indeed implies that the absolute heat of air is indefinitely greater than its specific heat; and certainly many difficulties could be explained on the supposition that the same thing holds of bodies generally, or that all the heat we can impart to or abstract from bodies bears no proportion to their absolute heats.

Hygrometry.

(*Trans. Roy. Soc. Edin.* vol. x. p. 195) are free from all such objections, and show that, under equal volumes and pressures, the specific heats of the different gases are equal, a result equally fatal to the conclusions which were deduced from the excessively complicated method of MM. Delaroche and Berard. If, therefore, the experiments of Desormes and Clement are so very erroneous for comparing the specific heats of different gases, why should we put any confidence in them for that of the same gas under different pressures?

Experiments somewhat similar to those just noticed have been made by MM. de la Rive and Marcet, and described in the *Annales de Chimie* for May 1829; but in an article on the same subject in the next number of that journal, M. Dulong has shown, that in these experiments, from their being made on an exceedingly minute scale, the mass of air operated on was so very small, compared with that of the vessel, that they do not warrant any definite conclusion at all. We are scarcely better satisfied with the method which M. Dulong himself has there employed for estimating the specific heats of the gases from the frequency of their vibrations, as supposed to be registered by a kind of wind-instrument coupled with wheel-work, and called a *sirène;* because that method involves several questions not yet cleared up. But what we particularly object to is, that no allowance is made for the tendency which it is natural to think the vibrations of the materials of the wind-instrument itself must have to increase the frequency of the vibrations of the gas under examination; an oversight similar to what, as we shall by and by see, pervades the usually received theory of sound. Nor can there be a doubt that the vibrations of strings, wires, &c. in musical instruments are influenced by the vibrations of the materials by which they are stretched.

Experiments for determining the constants.

Having completed the intended investigations, it may now be useful to give some account of the experiments to which we have several times alluded, for ascertaining the value and constancy of the ratio of m to n. We shall first give a familiar illustration of the principle, and then state more nearly the actual mode of experimenting. Suppose a vessel to be accurately closed, when occupied by air of the same temperature and pressure as that around it or in the apartment, and to be furnished with a gauge for showing any minute change of pressure. In this state let the apparatus be carried into another room of a little higher temperature, say m degrees warmer than the former; and then the gauge will soon indicate an increase of elasticity, which we may call m degrees. If the vessel admit of being now opened sufficiently, and shut again so promptly as just for the moment to allow the included air to regain the external or its original pressure, without affording time for its abstracting heat from the materials of the vessel, the gauge will in a little time indicate a second but much smaller increase of pressure, which we may call $m - n$ degrees. The reason of this may be traced in a general way to the well-known fact, that air of whatever density is cooled by dilatation. The gauge, while indicating m degrees, shows the included air to be denser than that in the second apartment; and therefore, on opening the vessel, the superior elastic force within expels a portion of that air, leaving the remainder of course rarer than that of the first room, though still a little denser than that of the second; because it has been cooled, as the result shows, $m - n$ degrees below the temperature of the second room. For at the instant of re-shutting the vessel, the elasticity of the included air is in equilibrio with the external pressure; but it must then be more dense than the air of the second apartment, otherwise, its temperature being lower, it could not balance the external pressure. On recovering therefore from the small and momentary depression of temperature, the excess of density shows itself by the gauge. The escape of a small portion of air while the vessel is open does not alter the result, because it only carries off its own heat. By this mode of operating, the ratio between the small quantities m and $m - n$ can evidently be ascertained with incomparably greater exactness than by any thermometer whatever. The distinguished German philosopher Lambert had long ago contrived to operate on air in such a way that it showed the changes of its own temperature; and no doubt it has been the uncertainty attending the employment of thermometers in more recent researches on air, that has led to such strange and paradoxical results, and which has called in the aid of so many fanciful hypotheses regarding the nature of heat. Indeed there is no time for a thermometer of any sort acquiring the minute change of temperature denoted by $m - n$.

Since we shall presently see that m is to n either exactly or very nearly as 4 to 3, it will conduce to greater simplicity if we now give this value to that ratio. But it is obvious, that during the small moment the vessel was open, the air which remained in it, having its temperature slightly depressed, could not lose heat, and had not time to gain any; so that the total heat in that remainder may be regarded as constant during the operation. Hence the same quantity of heat which had been sufficient to keep the air m degrees or 4° above its original temperature while confined in the vessel, shows itself to be only able, while again put under the original pressure, to maintain an excess of n degrees or 3° above that same temperature. The variation of heat, therefore, which would produce a given minute change, for instance, one degree in the temperature of air, and which variation is usually called its specific heat, must be one third greater when the air is free to change its volume under a constant pressure, than if confined in an inextensible vessel.

It is evident that the experiment would be essentially the same, if the vessel, in place of being brought from a colder apartment, were to have as much additional air injected into it as should make the gauge indicate 4° above the external pressure, after the temperature of the included air has settled to that of the room; the rest of the process, as to opening and promptly shutting again the vessel, being as already described. Now, in either method it is obvious, that at the instant of suddenly re-shutting the vessel, the included air, being brought to an equilibrium with the atmosphere, had, with reference to pressure, lost all the additional 4°; while, as the second indication of the gauge, viz. 1°, shows it had only lost 3° with regard to density, one of the lost degrees of pressure being therefore due to momentary depression of temperature. Hence, the height of the barometer, or whole pressure, is to the variation of pressure denoted by 4°, as p to dp. Also the height of the barometer, or whole density, is to the variation of density denoted by 3°, as ϱ to $d\varrho$. Consequently, $p : 3dp :: \varrho : 4d\varrho$.

Such is nearly the mode of experimenting followed by Mr Meikle, as detailed at length in the *Edinburgh Phil. Journ.* for April 1827, and more recently repeated with an improved apparatus, fully as large as the former one, which contained 2310 cubic inches, but with the advantage of having four apertures, amounting together to twenty-five square inches, which can be both opened and shut again so promptly, that the time of their being open is only a small fraction of a second. Something similar had been previously practised, though with a less perfect apparatus (*Journal de Physique* for Nov. 1819, p. 331), by MM. Desormes and Clement, and had likewise, at the desire of Marquis de Laplace (*Mécanique Céleste*, livre xii. chap. 3, and *Conn. des Temps* for 1825, p. 372), been adopted by MM. Gay-Lussac and Welter, who continued it through a great range both of temperature and pressure; but they do not make the simultaneous variations of density and pressure

Hygrometry.

exactly such, that $p : 3dp :: \varrho : 4d\varrho$, which is very nearly the relation obtained by Mr Meikle from a mean of many experiments, and with either apparatus; but they make $p : 3dp :: \varrho : 4{\cdot}1244d\varrho$. The difference is not very considerable; and the following consideration, we think, renders it extremely probable that the former is the true relation. Sir Isaac Newton has shown (*Principia*, lib. ii. prop. 23), that if in an elastic fluid the cube of the pressure vary as the $r + 2$ power of the density, the particles should repel each other with forces inversely as the rth powers of their distances; and similar investigations and results may be seen in other elementary works. Now, these experiments of the French philosophers just named make the cube of the pressure proportional to the 4·1244 power of the density, as is evident if we put 3 and 4·1244 in place of n and m in art. 3. Hence $r = 2{\cdot}1244$, and therefore the particles would repel each other with forces inversely as the 2·1244 powers of their distances; a law of which there is no known parallel in nature. But if the ratio of n to m were that of 3 to 4, and these numbers were substituted as indices in art. 3, we should have $\left(\frac{p}{p'}\right)^3 = \left(\frac{\varrho}{\varrho'}\right)^4$, or the cube of the pressure varying as the fourth power of the density; and consequently, the repulsion between the particles of the air would vary inversely as the squares of their distances, which is the only known law of repulsion, and most likely the only one which exists.

Particles of air repel each other with forces inversely as the squares of their distances.

It had long been well known in a general way, that when air has its volume or bulk changed so suddenly as to afford little or no time during the process for its either imparting heat to or receiving it from surrounding bodies, the pressure is at that instant changed in a much higher ratio than the density is. This was quite sufficient to render it certain, that whatever might be precisely the true law of repulsion, it must follow something very different from the reciprocal of the simple distance, which supposes the pressure and density to vary in the same ratio. For it was as well known, that during cases where the pressure has varied in the same ratio as the density, time enough has always elapsed for the air either imparting to or receiving from surrounding bodies as much heat as it may either have evolved by compression or absorbed by dilatation; because compression, by tending to warm the air, induces it to give out heat, and dilatation, by tending to cool the air, induces it to receive heat. But when, from cases in which the pressure had varied in the same ratio as the density, Newton inferred that the particles of air repelled each other with forces inversely as their simple distances, he was quite excusable; because the facts just noticed were not known in his time, nor were they indeed attended to till towards the end of last century. The like excuse, however, cannot so well be pleaded for Dr Dalton, who, in speculating on the constitution of the atmosphere so lately as in the *Phil. Trans.* for 1826, just adopts the law of repulsion deduced by Newton, and without making the slightest objection to it on the score now stated. The French savans, again, in having virtually made the repulsion vary inversely as the 2·1244 power of the distance, seem to have run a little into the opposite extreme. But when they adopted that conclusion, they were perhaps influenced a little by Laplace's theory of sound, which required something of the sort to help it out, and for which indeed the experiments of Gay-Lussac and Welter were purposely undertaken. The defect of the theory, we presume, lies rather in its not including the share which it is likely the re-action of the earth's surface has in accelerating the transmission of sound. For it seems reasonable to think, that since the air presses strongly on the earth's surface, it must, while propagating sound, both set that surface a vibrating, and, in return, have its own vibrations accelerated thereby; because the vibrations of the earth's surface should incline to be more frequent than those of air. Such at least seems to be the case with the vibrations of solids and liquids generally; though these again differ widely among themselves, and should of course affect the velocity of sound differently. According to this suggestion, the louder or the more intense the sound, the more fully will the earth's surface be brought into action, and consequently the greater, *cæteris paribus*, should be its accelerating influence. A similar defect, as we hinted above, seems to attach to the many attempts which have been made to determine the frequency of the vibrations of elastic fluids by means of wind-instruments; no allowance being made for the influence which it is likely the vibrations of the materials composing the wind-instruments have on the frequency of the vibrations of the gas under examination.

Probable defect in the theory of sound, and of the vibrations of gases.

We shall now enter on the consideration of hygrometers which are formed of materials comparatively free from decay, which are constant or consistent in their indications, and which, in short, seem in a great measure to possess the first five of the properties already specified, which Saussure considered necessary to a perfect hygrometer: as for his sixth, we regard it as supererogatory. The fact that humid air readily wets bodies which are colder than itself, such as stones and walls at the commencement of a thaw, must have been familiar to mankind from the remotest antiquity; though it has not been long known that dew or hoar-frost affords the most universal example of this all the world over; being moisture deposited on bodies which have been sufficiently cooled by radiation below the temperature of the incumbent air. The ancients appear to have conjectured that a copious deposition of moisture on cold bodies prognosticated bad weather; but the first step perhaps towards applying this principle to the construction of a hygrometer was made by the Florentine academicians, who having suspended in the open air a conical vessel filled with snow or pounded ice, supposed the humidity of the air to be proportional to the quantity of moisture which, being condensed on the exterior surface of this vessel, trickled down its sides, and dropt from the apex of the cone. This, however, could afford but a very vague estimate of the humidity of the air; because the quantity of moisture thus collected must obviously have depended in a great measure on the velocity of the wind; and such an estimate would be still more erroneous, or rather useless altogether, in the time of frost. The same idea was farther improved upon by M. Leroy of Montpellier, who, by dropping ice into water contained in a vessel with a bright exterior surface, gradually lowered its temperature, till dew began to be deposited from the contiguous air on that surface. Saussure substituted sal ammoniac for ice, and different salts have been employed by others for the same purpose. The temperature to which the vessel is thus brought at the moment of incipient deposition, is obviously the temperature to which, if the air were cooled under the same pressure, the vapour in it would be in a state of saturation, or ready to deposit dew upon any thing in the least degree colder than itself. Such temperature is therefore denominated the *dew-point*. Did the air, in cooling, undergo no diminution of volume, it would not be brought to a state of saturation with moisture, till it were cooled below t, the temperature of the air through a range greater nearly in the ratio of $1 + \frac{t + 448}{8600}$ to 1 than that which brings it to the dew-point. Some writers do not seem aware of there being any difference between these points of saturation; and others have such confused notions of it, that not unfrequently they transpose them; though no-

More durable class of hygrometers.

thing is more certain than that these temperatures cannot be the same, and that the dew-point is the higher of the two. For if t be the actual temperature of the air, and t'' the dew-point, since the pressure is the same in both cases, the actual density of the air is to its density when cooled to the dew-point, in the inverse ratio of $t + 448°$ to $t'' + 448°$, as was shown above regarding the expansion of air; but since all elastic fluids yet tried expand or contract at the same rate by the same change of temperature, the density of the vapour at the dew-point must therefore be greater in the above ratio than its density at the actual temperature, which is the same as its density would be were the air cooled without shrinkage. This, however, is not meant to prove the above ratio to be the very law of nature.

The following table is for facilitating computations of this kind. The first column is the Fahrenheit temperature t; the second the maximum force f of aqueous vapour for that temperature; the third the corresponding weight of moisture in a cubic foot expressed in grains. The fourth column, computed from the formula $\frac{t + 448}{480}$, shows the ratio in which an elastic fluid is expanded or contracted by having its temperature changed from 32° to t; and this column, being everywhere in the ratio of the temperature reckoned from — 448°, may therefore denote either the volume of a given mass of elastic fluid under a constant pressure, or the pressure under a constant volume, the unit of each being at 32°. The second column is computed from the formula which M. Biot has deduced from Dr Dalton's experiments, viz.

$$\log. f = 1{\cdot}4771213 - {\cdot}0085412197\,(212 - t) - {\cdot}0000208109\,(212 - t)^2 + {\cdot}0000000058\,(212 - t)^3;$$

but we have slightly increased a few of the numbers next zero, to correspond with the experiments of Gay-Lussac, because those of Dr Dalton did not go lower than 32°.[1] Vapours of all sorts, so far as yet tried, are found to observe the general laws of elastic fluids, in having the density directly as the pressure, and inversely as $t + 448$; and from the experiments of Dr Rice it appears that a cubic foot of water at 40° weighs 437,272 grains; and this again M. Gay-Lussac found to be 1700 times heavier than a cubic foot of aqueous vapour at 212°, which therefore weighs 257·2188 grains. Hence, to obtain the numbers for the third column, we have

$$\frac{30}{212 + 448} : \frac{f}{t + 448} :: 257{\cdot}2188 : \frac{5658{\cdot}81 f}{t + 448},$$

the number of grains in a cubic foot of aqueous vapour in a state of saturation, at the temperature t.

But when the vapour is not in a state of saturation, as, for instance, when the actual temperature of the air is 60°, and the dew-point only 40°, we proceed thus:—Opposite 40° in the first column of the table we find ·2644 inch in the second for the actual force of vapour in the air; but from what has been shown above regarding the expansion of elastic fluids, the density at 60°, corresponding to a force of ·2644, must be less than if the temperature were 40°, in the ratio of 40 + 448 to 60 + 448, or of 1·0167 to 1·0583 (viz. using the numbers in the fourth column opposite 40° and 60°). We must therefore reduce in that ratio the maximum weight in a cubic foot at 40°, namely, 3·066 grains, which will make it $\frac{1{\cdot}0167}{1{\cdot}0583} \times 3{\cdot}066 = 2{\cdot}945$ grains for the actual weight of moisture in the air, corresponding to a temperature of 38°·8; so that, had the air been cooled down to 38°·8, without shrinkage, or under the original volume, the vapour would have been brought to a state of saturation. The temperature 38°·8, as already observed, is lower than the dew-point by very nearly $\frac{t + 448}{8600}$ times the difference between the dew-point and the temperature of the air. Thus $38°{\cdot}8 = 40° - (60 - 40)\frac{508}{8600}$; which affords a ready mode of computing this lower point of saturation without the aid of any table.

It is much more convenient to use the grains in a cubic foot than the small fraction of a grain in a cubic inch; because the latter requires more figures to express it with the same accuracy. But it is not so much from pretensions to superior exactness that we use so many decimal places in these columns, as to render the differences of the numbers more uniform, which is of consequence when there is any occasion for taking proportional parts, or interpolating between them.

---

[1] The committee of the Royal Academy of Sciences at Paris, who made a very elaborate and extensive series of experiments on the force of steam in 1829, as described at length in the *Ann. de Chim.* for January 1830, give the following formula:

$$e = \left(1 + {\cdot}007153\,(T - 100)\right)^5,$$

where e is the elasticity in atmospheres, and T the temperature centigrade. This expression, however, becomes far too small at low temperatures, and vanishes altogether at the freezing point of mercury. M. Roche, again, makes

$$\log.\ e = \frac{T - 100}{T + 266{\cdot}67} \times 5{\cdot}48.$$

But neither can any expression of this form be the law of nature; because, besides erring considerably at temperatures within the range of observation, it would require the density of saturated steam to reach a maximum, and then decrease; so that some of it would become liquid by the addition of more heat, which is quite incredible. Indeed every formula which, so far as we know, has yet been published, for expressing the force of steam, is liable to some such objections.

Table of the Force, Weight, and Ratio of Expansion, of Aqueous Vapour in a state of Saturation, from 0° *Fahrenheit to* 100°.

Daniell's hygrometer.

The principles already explained will make the construction and use of Professor Daniell's elegant instrument easily understood. It is represented in its full dimensions in fig. 8, Plate CCXCV. where *a* and *b* are two thin glass balls of 1·25 inch in diameter, connected by a tube having a bore of about ·125 inch. The tube is bent at right angles over the two balls; and the arm *bc* contains a small thermometer *de*, whose bulb, which is of an oval form, descends into the ball *b*. This ball having been about two thirds filled with ether, is heated over a lamp till the liquid boils, and the vapour issues from the capillary tube *f* on the under side of the ball *a*. The vapour having expelled the air from both balls, the capillary tube *f* is hermetically closed by the flame of a lamp. This process is familiar to those who are accustomed to blow glass, and may be known to have succeeded after the tube has become cool, by reversing the instrument, and taking one of the balls in the hand, the heat of which will cause the ether to boil rapidly, and pass wholly over by distillation into the other ball. The ball *a* is now to be covered with a piece of muslin. The stand *gh* is of brass, and the transverse socket *i* is made to hold the glass tube in the manner of a spring, allowing it to turn and be taken out with little difficulty. Another small thermometer *kl* is inserted into the pillar of the stand. The manner of using the instrument is this:—After having driven all the ether

Hygrometry. into the ball b by the heat of the hand applied to the ball a, the instrument is to be placed at an open window, or out of doors, with the ball b so situated as that the surface of the liquid may be upon a level with the eye of the observer. A little ether is then to be dropped upon the covered ball. Evaporation immediately takes place, which, by abstracting heat, cools the ball a, and causes a rapid and continuous condensation of the ethereal vapour within it, together with a diminution of pressure. The consequent evaporation from the included ether produces a depression of temperature in the ball b, the degree of which is measured by the thermometer de. This action is almost instantaneous, and the thermometer begins to fall in two seconds after the ether has been dropped. A depression of thirty or forty degrees is easily produced, and the ether may be sometimes seen to boil when the thermometer is below the zero of Fahrenheit. So soon as the ball b is cooled by this artificial process down to the dew-point of the surrounding air, a condensation of the atmospheric moisture takes place upon its surface, and this first makes its appearance in a narrow ring of dew on a level with the surface of the ether. The temperature at which this occurs, viz. the dew-point, is to be carefully noted. A little practice may be necessary to seize the exact moment of first deposition, but certainty is very soon acquired. It is advisable, when the ball b of the instrument has been made of transparent glass, to have some dark object behind it, such as a house or a tree, because the cloud is not so readily perceived against the sky or open horizon. The depression of temperature is first produced at the surface of the liquid, where evaporation takes place, and the currents which immediately ensue to effect an equilibrium are very perceptible. We may here remark by the by, that since the covered ball a must be fully the colder of the two, there is reason to think, that while it is throwing off and furnishing latent heat for ethereal vapour, it is very likely condensing aqueous vapour and absorbing its latent heat. The bulb of the enclosed thermometer de is but partially immersed in the ether, with the view of making the line of greatest cold pass through it; but this we shall find to be a faulty arrangement. In very damp or windy weather, the ether should be very slowly dropped upon the ball, otherwise the descent of the thermometer will be so rapid as to render it extremely difficult to be certain of the degree at which deposition commences. In dry weather, on the contrary, the ball requires to be well wetted more than once, to produce a sufficient cold. If at any time there should be reason to suspect the accuracy of an observation, it may, according to Mr Daniell, be corrected by observing the temperature at which the dew upon the glass again disappears: the mean of the two observations should give the true result; because their errors, he thinks, if any, should lie in contrary directions. This, however, is on the supposition that the error lies all with the observer, and that the instrument itself is faultless; whereas we shall shortly see reason to conclude that, unless it be agitated during an observation, it has a tendency to give the dew-point too high, owing to every part of the bulb of the included thermometer not being alike exposed to the cooling effects of the ether. It is obvious that care should be taken not to permit the breath to come into contact with the glass.

Mr Daniell's hygrometer may also be applied to artificial atmospheres, and experiments on air or other gas confined in a vessel. Fig. 9 represents a receiver and hygrometer prepared for this purpose; and the following is the manner in which they were fitted up. A hole is perforated in the side of the receiver, through which the tube proceeding from the ball within it containing the thermometer is first passed, and then welded by means of a lamp to the tube attached to the other ball outside the receiver. The stem is secured in the hole of the receiver with cement, the ether is boiled, and the capillary tube closed, as before described. The external ball is then to be covered with muslin, and ether being dropped upon it, the consequent evaporation produces, in the manner already explained, a corresponding degree of coldness in the internal ball. The state of humidity within may be ascertained by noting the temperature at which dew begins to appear on that ball. In delicate experiments, a lighted taper in a glass lantern, placed behind the instrument, renders the deposition more easily visible, and ensures accuracy. The hygrometric properties of any substance, or its power of absorbing moisture, may thus be readily estimated, by placing it under the receiver, and marking the fall which it occasions in the dew-point. By means of this apparatus Mr Daniell made a variety of experiments, from which it appeared, as Deluc, Dalton, and others had asserted, that the quantity of moisture which can exist in a given volume depends solely on the temperature, and is not influenced by the presence or density of air or other elastic fluids, provided no chemical action occur.

Attempts at improving Daniell's hygrometer.

There have been various attempts to improve upon Mr Daniell's hygrometer, or to contrive a more simple one which should serve the same purpose. About ten years ago, several instruments, essentially the same in principle, though differing widely in contrivance from Mr Daniell's, were proposed in different quarters with this view. The leading features in their construction are, to cover partially the bulb of a large thermometer with muslin, silk, cambric, or the like; to wet this with ether; and to observe at what degree of that thermometer moisture is deposited on the uncovered part of its bulb. A more simple construction for directly observing the dew-point was scarcely to be expected, but unfortunately it was soon found to be very fallacious. For, owing to the uncovered part of the bulb not being directly exposed to the cooling effects of the evaporation, its temperature, viz. the dew-point, is generally several degrees higher than the mean temperature of the bulb, or that indicated on the scale of the thermometer; so that such instruments generally give a dew-point considerably below the truth, and the error is found to be greater when the bulb is of an elongated or cylindrical form than when spherical. This error may be made manifest in several ways, but the preferable one seems to be to observe the dew-point at the same time by the method of Leroy, as improved by Saussure and Dalton, namely, to cool down water in a bright vessel by dropping in colder water, ice, or salts, and to stir it with a thermometer till dew just begin to appear on the exterior surface of the vessel. The thermometer will at that instant indicate the dew-point with great accuracy if the vessel is thin, and especially if of metal.

Defect in Daniell's hygrometer.

The discovery of such a defect in these instruments led to a careful examination of Mr Daniell's hygrometer by the same test; and the result was, that it is liable to the contrary error of giving the dew-point above the truth. For since in that instrument the deposition occurs in a narrow ring or zone on a level with the surface of the enclosed ether, which, during the cooling, is considerably colder at the surface than beneath; and since the elongated bulb of the enclosed thermometer is only half immersed in this ether, it is evident that scarcely half of this bulb is subjected to so great a cold as that which produces the deposition of moisture. As to any cooling effect of the ethereal vapour on the upper half of the ball, it must be extremely feeble compared with the cooling influence of that liquid itself, as is evident from the effect which agitating the ether round the whole bulb of the thermometer has in lowering its indication. In place therefore of an observation with this hygrometer being

Hygrometry.

"simple, expeditious, easy, and certain," it is evident, that unless the instrument is shaken, or the observation made so slowly and cautiously as to allow the bulb of the included thermometer time to become all of one temperature, it cannot fail to give the dew-point too high; so that the more clever or expeditious any one fancies himself to be in using this instrument, so much the farther is his observation likely to be from the truth.

Adie's hygrometer.

A substitute for this instrument, preferable to any of the foregoing, has been contrived by Mr John Adie, and is described in the *Edinburgh Journal of Science* (new series, vol. i. page 60). A thermometer having a small bulb is enclosed in an exterior bulb or case of black glass, which is covered with silk, excepting a small space about a quarter of an inch in diameter, where the deposition is to be observed. The space between the outer and inner bulbs is nearly filled with any liquid not liable to freeze by the depression of temperature required for finding a dew-point, as alcohol, mercury, linseed oil, &c. When an observation is to be made, ether is applied to the silk, and the instrument is kept in a state of gentle agitation, to render the inner and outer bulbs all of one temperature. With this instrument Mr Adie obtained constant results, not differing more than half a degree from Leroy's method, already described. The following table exhibits the results in twenty-eight cases, as observed with five different dew-point instruments. The first column is the temperature of the air; the second the dew-point, as observed by Leroy's method; the third, by Mr Adie's instrument; the fourth, by Mr Daniell's; the fifth, by the large thermometer, having a round bulb partially covered with muslin; the sixth, by the same kind of thermometer with an elongated or cylindrical bulb.

It has been objected to Mr Adie's instrument, that the dew being formed alike quite over the uncovered part of the outer bulb, it does not exhibit that fine contrast between the clean and bedewed parts which Mr Daniell's bulb does, and which renders the commencement of deposition better defined. But an equally good contrast, we presume, might easily be produced by forming a small blister air-bubble, or other double spot, in the glass or metal of which the cover is made. No dew would form on this spot, at least till long after it had begun on the adjacent surface. Another objection is, that the air immediately round the spot where the deposition occurs is strongly impregnated with ether, which may possibly have some effect on the commencement of deposition, especially at temperatures and pressures beyond the range of these experiments, and where the dew-points are much farther below the temperature of the air.

Pouillet's hygrometer.

M. Pouillet has produced a different substitute for Mr Daniell's hygrometer. The stem of a thermometer descends through, is closely fitted into, and secured in, a perforation in the bottom of a small silver cup; the bulb only of the thermometer being left above within the cup. When this instrument is to be used, ether is poured into the cup till it cover the bulb, and the consequent evaporation producing cold, causes a deposition of dew in the form of a narrow ring on the outside of the cup, and on a level with the surface of the ether. But owing to the whole bulb of the thermometer not being exposed to so great a cold as that at the surface of the ether, and which causes the deposition of dew, we should suspect this contrivance of being liable to give the dew-point too high, though not perhaps to the same extent as Mr Daniell's. There is likewise reason to think that the cup, if deep, would retard the evaporation, while, if shallow, it could not prevent the wind from blowing the ether over its sides. But perhaps both these inconveniences might be avoided by having a bit of muslin stretched close over the surface of the ether, and as if swimming in it; though this again, by retarding the circulation of the ether in the cup, might tend to augment the error in the indication of the thermometer.

Proposed construction.

We have sometimes thought that a construction combining the advantages, and avoiding the defects, of these several contrivances, might be obtained, without departing so far from the form of Mr Daniell's instrument. Thus, if the uncovered bulb *b*, which contains the ether in his hygrometer, had a blister or air-bubble formed in the glass, the exterior surface of this would remain dry or free from dew, at least till the cold went far below the dew-point; so that, without running any risk of obliterating the contrast between the clear and bedewed parts of the bulb, we might agitate the instrument sufficiently to ensure that the thermometer within should indicate the temperature of the bedewed surface. When the exterior bulb is of metal, it would be equally easy to make a small part of its side double for the same purpose. There would then be no need for bending the tube, to keep the re-condensed ether from running down and cooling the upper half of the exterior bulb, if indeed that was the design of bending it; for Mr Daniell assigns no reason either for bending the tube or having it so very long. But it is evident, that by keeping the tube straight and much shorter, the instrument would be greatly simplified, and rendered much less liable to accidents. In this form, too, it could be as readily suspended perpendicularly as before, by merely slipping the tube into the forked end of a branch proceeding from the top of the pillar. Perhaps it may be said that the design of the tube's being so long was to keep the ethereal vapour at a distance from the spot where dew is to be deposited; but this, if intended, is effectually defeated by the bending of the tube, which brings the bulbs as near each other as if the covered one were only a little above the stem of the enclosed thermometer. Whether any chemical action may take place between the aqueous and ethereal vapours, which could sensibly affect the deposition of dew, we could not pretend to say; but it is natural to think that the expansive force of the ethereal vapour should distend or dilate the air and moisture, which would tend to lower the dew-point. Mr Adie's experiments, it is true, seem to give the dew-point the same as by Leroy's method; but in his cases given above, the dew-point is generally so little below the temperature of the air as to have required very little ether to produce the requisite cooling; so that it may have been owing to the comparatively feeble state of the ethereal vapour that the dew-point was not sensibly affected; or possibly the chemical and mechanical effects of the ether on the dew-point might be opposed to each other. But it is surely more safe to avoid any risk of this sort altogether. With any sort of dew-point instrument, it must be difficult to observe at low temperatures the precise degree at which the vapour is cooled to saturation, owing to its extreme tenuity. For unless the bright surface be sensibly colder than the air to which it is presented, the commencement of deposition is not likely to be readily noticed in very attenuated vapour.

Hutton's hygrometer.

Dr James Hutton seems to have been the first who thought of applying the comparison of the different indications which a thermometer exhibits in a dry and in a moistened state to the purposes of hygrometry. With this view he had a thermometer enclosed in a glass tube hermetically sealed, which he first held in a proper situation till it acquired and showed the temperature of the air. Then having dipped it in water, he held the end of the tube which contained the bulb towards the current of air, and observing how much the thermometer had been lowered by evaporation, he regarded the depression as a measure of the dryness of the air. This view of the matter, though not quite correct, was a wonderful step, considering how little was then known regarding the laws which regulate the diffusion of aqueous vapour in air or other elastic fluids. But instead of employing only one thermometer, and enclosing it, as Dr Hutton did, in a glass tube, it is found not only more convenient, but conducing to greater accuracy, to use two thermometers; one of which notes the actual temperature of the air, while the other, having its bulb covered with muslin, silk, cambric, or the like, and moistened with pure water, shows the temperature as depressed by evaporation. We have found it to be still more convenient to have both thermometers mounted on one broad and doubly graduated scale, and both might be of the self-registering sort. Soft paper has sometimes been used to cover the thermometer; but if it contain any soluble matter, it is apt to render the water impure, and vitiate the results. In short, whatever sort of covering is used, care should be taken to have it both clean and free from every thing which may affect the purity of the water. Thus the thermometer is found to be much less cooled by evaporation when moistened with brackish water than with fresh. Some cover the bulbs of both thermometers, with the view of having the surfaces as nearly alike as possible, and of one colour, to obviate any unequal effects of light or radiation; the nearer to white of course the better.

This sort of hygrometer, after having been sadly neglected for thirty years, at least in any thing near its original form,[1] has at length become an object of interest both here and on the Continent, particularly in Germany, where it has been dignified with the name of the *Psychrometer*. The British Association too has repeatedly expressed a desire to receive a satisfactory exposition of the theory of this instrument, and has requested observers to institute comparative experiments between its indications and the corresponding dew-points, as obtained by the methods already described. So that, when once comparisons of this sort have been made in circumstances sufficiently varied for the different states of the air, this hygrometer, from the durability and simplicity of its construction, the extreme facility with which it can be used, and the consistency of its indications in like states of the air, bids fair to come into more general use than any other; and this, we should think, is likely to be the case in a very few years. One of its most remarkable features, and which adds greatly to its value, is, that its indications are scarcely affected by any ordinary wind. They are, however, as will be noticed after, somewhat under the influence of the atmospheric pressure, but so slightly, that at the same place variations of pressure may in ordinary cases be neglected. When the moist thermometer is below 32°, about an eighth part of its depression below the temperature of the air is owing to the expense of heat for liquefying the ice previously to evaporation; the heat of liquidity being about a seventh part of the latent heat of the vapour; but this is a point which, so far as we know, has not yet been examined by any direct experiments.

When this instrument is first exposed to the drying influence of air, in which the aqueous vapour is not already in a state of saturation, evaporation takes place, and lowers the temperature of the moist bulb, by abstracting heat from it for the formation of additional vapour; but a limit is soon set to the fall of temperature by the surrounding air, which, in successively touching the wet and colder surface, imparts heat to it; and also no doubt by the warmer surrounding bodies throwing in a little heat upon the colder bulb by radiation. The heat thus imparted and thrown in is next to all we can think of as being continually supplied to the moist surface, and spent in the formation of new vapour, the supply being of course exactly equal to the expenditure, which depends on the drying influence of the air; and so does the difference of temperature, though the precise relations between them have not yet been determined. It might indeed be supposed that the stem of the thermometer should convey a little heat to the moist bulb; but the stem being of glass, is a bad conductor, and any heat which it supplies must be very inconsiderable, since it makes no sensible difference whether we apply a wet covering to the bulb alone, or continue it along a part of the stem. However, in the *Edinburgh Encyclopædia*, art. HYGROMETRY, Dr Anderson advances the doctrine, that the moist bulb itself furnishes all the heat spent in the formation of new vapour; whereas we cannot conceive how it can continue to furnish the smallest portion of heat after the process has fairly commenced, any more than a hot iron could continue to furnish heat to the air after it has been cooled down to the temperature of the air. Dr Anderson has, in the same article, and afterwards in different volumes of the *Edinburgh Phil. Jour.* (first series), given a variety of investigations connected with the use of the moist-bulb hygrometer; but as they involve the idea that the capacity of air for moisture is, *cæteris paribus*, proportional to the barometric pressure, his results necessarily diverge widely from the truth, when applied to cases materially different from those on which they are founded.

As already mentioned, the extent of the depression of temperature is scarcely affected by any ordinary wind; but unless the heat which surrounding bodies throw in

[1] A description of the late Sir John Leslie's hygrometer will be found under the article METEOROLOGY

by radiation on the colder bulb be quite inappreciable, this constancy of depression, so far from proving that the cooling influence of evaporation is independent of the wind, would rather argue that it is less as the velocity of the wind is greater. For since evaporation increases with the wind, while radiation is believed to be independent of it, it follows that the heat supplied by radiation not increasing in the same ratio as the expenditure or new vapour does, the depression, in place of being constant, as it is found to be, ought to increase with the velocity of the wind. Hence either the heat supplied by radiation is inconsiderable, or, which is more probable, the cooling influence of evaporation is less as the velocity of the wind is greater. From experiments described by Mr Meikle in the *Edinburgh Phil. Jour.* for January 1827, it appears that giving a pretty rapid motion to a moist thermometer in air confined over sulphuric acid, tended considerably to increase the depression of temperature; but it may be questioned whether this was not owing to the agitation of the apparatus enabling the acid to render the air drier.

Philosophers are by no means agreed regarding the theory of this instrument, which, as we shall afterwards see, is involved in great difficulty and obscurity; but this is of less consequence, since a complete theory does not seem necessary to enable us to apply it to hygrometric purposes. For when once the dew-points corresponding to a sufficient variety of indications of the wet and dry thermometers and of the barometer have been well ascertained, a table of dew-points may be constructed from them, having for its entries or arguments the indications of the wet and dry thermometers, corrected, if necessary, for the particular pressure; so that, when aided by such a table, the indications of the wet and dry thermometers, and of the barometer, may obviously give us the dew-point, whether we know any thing of the theory or not.

The results of experiments determining the dew-point for a considerable number of indications of the wet and dry thermometers, and under various pressures, though principally at pretty high temperatures, are given in a Calcutta journal, *Gleanings in Science*, Nos. II. and III. 1829, and in the *Edinburgh Phil. Jour.* for October 1833, from which we have obtained the following table. The sixth column is derived from the formula

$$f_{t'} - \frac{(f_t + \cdot 66372)(t - t')}{175\cdot 438 f_t} = f_{t''},$$

where t is the Fahrenheit temperature of the air, t' that of the moist bulb, and t'' the dew-point; and f_t, f_{t}', f_{t}'' are the forces of aqueous vapour in a state of saturation at these temperatures respectively.

The dew-points in the sixth column do not differ very materially from observation; but the temperatures from which they were computed had first to be corrected for the barometric pressure, being different from thirty inches. The precise rule for estimating such a correction is as yet unknown; but it appears that, for the same temperature of the moist bulb, the difference between it and the dry thermometer, when the pressure amounts to thirty inches, is to their difference under any other pressure B, nearly in the inverse ratio of 57 to 27 + B. On this supposition, $t - t'$, the observed depression in the fourth column, before being used in the formula, has been multiplied by $\frac{27 + B}{57}$; and the difference between the product and $t - t'$ has likewise been applied, with its sign changed, as a correction to t, the temperature of the air. Although the temperature of the moist bulb is the one which is more immediately affected by pressure, it is considered easier to compute a tolerable correction to be applied to the other thermometer, so as still to lead to the same result. Some account of experiments relating to this will be found under the article EVAPORATION; though, perhaps, owing to the greater dryness and small volume of air operated on, the effect of pressure in most of the experiments there described seems to be greater than in the open air.

A considerable number of experiments on the dew-points corresponding to the indications of the moist and dry thermometers, though only between the temperatures of 69°·5 and 56°·25, are given in the *Edinburgh Phil. Jour.* for October 1834; but being made under the ordinary pressure, they throw no light on the effects of different pressures; and, considering how little the dew-points go below the temperature of the air, these experiments can scarcely be said to agree so well, either among themselves or with the formula, as the other 15 given above. The author supposes the discrepancies to be owing to the uncertainty attending the use of Daniell's hygrometer, with which they had been observed.

By means of the preceding formula for expressing the relations between the temperatures t, t', t'', the same ingenious author has computed the following table of dew-points, which, however, we have arranged in a more compact form, and curtailed considerably. For since it seems better to leave extreme cases, and such as are of rare occurrence, to be computed by some formula, than to swell out the tables to embrace them, we have omitted all that part of the table which went above the temperature of 100°; and really wish we had been possessed of data to have authorized its extension downward, if possible, to the zero of Fahrenheit. The argument or entry on the left-hand side is the temperature of the air, while the excess of that over the temperature of the moist bulb is the argument on the top. But if at the time of observation the barometer has differed from thirty inches, these arguments should first be corrected by means of the small table in the lower right-hand corner, which is to be entered at the bottom with the barometric pressure, and on the right side with the observed difference between the wet and dry thermometers. The number thus obtained from this small table is to be subtracted from both the arguments of the large table when the pressure falls short of thirty inches, and added when it is greater.

Table of Dew-Points.

Hygrometry. Hygrometric scales.

A different mode of obtaining from the same data, not only the dew-point, but likewise the force, weight, &c. of moisture in the air, has been proposed by Mr Meikle, in the *Edinburgh Phil. Jour.* for July 1834 and April 1835, to consist of certain graduated lines or scales delineated on a plane, and are to be used by laying over it any thing most convenient which will form a straight line, such as a common ruler, a thread stretched, &c. This sort of scheme is not deduced from theory, but merely from observation, and seems to admit of being varied very considerably in its form; though it is likely that, when more numerous and certain data have been obtained, some particular modification will be found to have the advantage of the rest. For we are not aware of any accurate experiments having yet been made on the moist-bulb hygrometer at low temperatures. Plate CCXCVI. shows one of the various forms proposed for this purpose in the articles just cited, though it is not here followed up in every particular. The mode of using it will be pretty evident from inspection. If a straight line or ruler be applied to the temperature of the air on the left-hand curve, and at the same time to the temperature of the moist bulb on the oblique straight line, it will both mark the dew-point on the scale so named on the right, and at the same time show on the other scale, a little farther to the right, the weight of moisture actually diffused in a cubic foot of the surrounding air, in grains and tenths of a grain. The like degrees of temperature on the different scales are everywhere disposed in a horizontal straight line. If otherwise arranged, these scales could not be used by simply laying a straight line over them, as is evident if we take a case in which the vapour approaches saturation. The oblique straight line is an asymptote to the two curves nearest it, which are meant for hyperbolas; but the divisions for degrees of temperature decrease a little downward in the lower part of the figure. It has been objected, that the hyperbolas would not suit air absolutely dry, and a dew-point infinitely low; but it is shown at length in the *Edinburgh Phil. Jour.* for April 1835, that no such case can ever occur in using the moist bulb, and that this scheme is not restricted to hyperbolas. The results obtained by this method sometimes differ considerably at low temperatures from those of the large table of dew-points; but we know of no experiments to decide how far any of them may be right at low temperatures.

We have thought it better at present not to encumber the diagram with what was originally proposed in this scheme as a correction for pressure, because there seems still to be some uncertainty regarding the precise allowance. But when the barometer differs from thirty inches, the approximate correction, which was already noticed above, may be employed here. It is equivalent to using $t' + \frac{B + 27}{57} \times (t - t')$ in place of the actual temperature of the air. The force of vapour corresponding to a known dew-point is sufficiently well ascertained for ordinary purposes; but we have likewise at present omitted the scale proposed for it, in order not to render the scheme too complicated at its first outset. The same allowance for frost will of course be required here as in any other method with the moist-bulb hygrometer.

Were this project fully realized, that is, if by merely laying a ruler across the plate in the manner above mentioned, the dew-point and weight, &c. of the vapour in the air could be indicated at once, and without computation, it would obviously be one of the most convenient methods yet employed for the purpose.

Theory of the moist bulb hygrometer.

We shall now endeavour briefly to sketch out a few steps towards an investigation of the relation between the dew-point and the corresponding indications of the moist-bulb hygrometer, and have to regret that the present imperfect state of the data does not warrant or enable us to render it more complete. It was shown above, that the value of any particular degree on Fahrenheit's scale of an air-thermometer, that is, the increment or decrement of heat necessary to produce a change of one degree by Fahrenheit's scale, in the temperature of a given mass of air under a constant pressure, will be inversely as the distance of that degree from $-448°$. But when the volume and pressure are both constant, with a variable mass, the increment, decrement, or specific heat for one degree of Fahrenheit, will, so far as depends on change of temperature, be inversely as the square of the distance of that degree from $-448°$, viz. in the ratio compounded of the mass or density of the air and the value of a degree, each of which varies inversely as the temperature reckoned from -448. For we have likewise shown above, that the specific heat of a given volume of air is, *cæteris paribus*, as its density. Strictly speaking, it is obviously the fluxion of the heat which varies in this manner. Hence, so far as depends on change of temperature, the fluxion of the quantity of heat in a cubic foot of air cooling under a constant pressure at the temperature t, will be directly as $-dt$, and inversely as $(t + 448)^2$. It may therefore be denoted by

$$\frac{-A\,dt}{(t + 448)^2}$$

where A is a constant.[1] The fluent of this taken between the temperatures t and t' is

$$\frac{A(t - t')}{(t + 448)\,(t' + 448)},$$

which is the heat lost by the cubic foot of air while its variable mass is cooling under a constant pressure from t to t'. Hence, if the specific heat of a cubic foot of dry air of thirty inches pressure, and confined in an inextensible vessel at 32° F. be reckoned unit, and of course only three fourths of what it would be were the pressure constant, the value of A for the cooling of air under any constant pressure B, must be such that three fourths of it may equal the denominator in the above formula, when $B = 30$ and $(t + 448)\,(t' + 448) = (32 + 448)^2$;

$$\text{so that, } A = \tfrac{4}{3}\,(480)^2 \times \frac{B}{30}.$$

Now, from Dr Haycraft's experiments, it appears that at the same temperature the specific heats of all elastic fluids, and mixtures of them, so far as yet tried, are equal under equal volumes and pressures; and we have shown above, that the specific heat of a cubic foot of air, under a constant pressure, is directly as its density and inversely as its temperature reckoned from $-448°$. Combining these together, it follows that the specific heat of a cubic foot of elastic fluid is directly as the pressure and inversely as the square of the temperature reckoned from $-448°$; so that, at the same temperature, it is as the pressure simply. It will therefore come to the same thing if, in place of taking the sum of the separate specific heats of air, and of the vapour previously in it, we suppose either to have the joint pressure of both, which will equal that of the atmosphere. Consequently, the heat which a cubic foot of air and vapour at the temperature t would impart to the wet and colder surface, while cooling through $t - t'$ degrees, under the constant pressure B, will be

[1] The fluxion of the heat due to the fluxion of the mass, which is the same with the absolute heat in the increment of the mass, is a very different thing, being positive whilst this is negative; nor does it at all pertain to the specific heat.

$$\frac{\frac{4}{3}(t-t')\,(480)^2 \times \frac{B}{30}}{(t+448)\,(t'+448)}.$$

This perhaps would require to be slightly modified, for the mechanical influence of the new vapour which enters into the air during the observation.

Difficulties in the way of solving this problem.

We should have been happy to have completed an investigation of the relation between the dew-point and the indications of the moist-bulb hygrometer; but in endeavouring to prosecute it farther, we were met by difficulties which we suspect have been in a great measure overlooked by those who profess to solve the problem with perfect ease. Thus, if we suppose the depressed temperature to extend unaltered to a certain distance from the moist surface, and then all at once to change into the actual atmospheric temperature, is not this to assume an abrupt transition of temperature having no known parallel in nature, especially where the cooling process proceeds so slowly? We cannot comprehend, for instance, how the moist bulb, at a temperature of 70°, could be surrounded by a shell of air also exactly at 70° throughout its whole thickness, while the air immediately outside of this could be at 90°. Nor is there greater probability that the saturated vapour terminates abruptly, or that both terminate exactly at the same distance. Now, if neither the depressed temperature nor the new vapour terminate abruptly or at the same distance, is there any thing known of the nature of the law according to which either the one or the other decreases in the actual circumstances? Until some light is thrown on questions like these, every thing in the shape of a solution of the problem must rest in a great measure on conjecture; no matter how well successive trials and alterations may bring such an empirical solution apparently to agree with the phenomena. We should think it highly probable that the air enveloping the moist bulb is in a state of continual intermixture similar to that of a fermenting liquor; but how such a state of the air and humidity, if it exist, could be expressed algebraically, we cannot pretend to say.

Theoretical estimate of the latent heat of aqueous vapour.

Another point which, we presume, has not been sufficiently attended to in attempts to solve this problem, is the nature of the latent heat of aqueous vapour, particularly the manner in which it probably varies in different circumstances, and the relation which it bears to its own specific heat and that of air. These we shall now endeavour to examine, in conformity with the foregoing investigation respecting the relations of air to heat, though we can scarcely accomplish this so independently of hypothesis as we did in that case.

When detached from their generating liquids, steam or aqueous vapour, and all elastic fluids yet tried, expand by heat at the same rate as air does, and, like it, observe the law of Boyle, by having the force at the same temperature proportional to the density. But since the second principle above stated regarding the *constancy* in the ratio of the specific heats, or of m to n, seems to be closely connected with the rate of expansion and the law of Boyle, analogy renders it extremely probable that it likewise belongs to all gaseous bodies. Besides, Dr Haycraft's experiments for comparing the specific heats of gases (*Edinburgh Phil. Trans.* vol. x. p. 195, and *Philosoph. Mag.* for September 1824, p. 200) afford a farther presumption in favour of this; for they go far to establish as another general law, that under equal volumes, pressures, and temperatures, all elastic fluids have equal specific heats. His apparatus is incomparably the best which, so far as we know, has been applied to the purpose. That of Delaroche and Berard was so unnecessarily complicated, that we cannot adopt their results. Now, from what we have already quoted from Newton (*Principia*, lib. ii. prop. 23), it readily follows that, if the repulsion between the particles of an elastic fluid vary inversely as any given power of the distance greater than unit, the second principle above mentioned holds respecting that fluid; or its specific heat under a constant pressure exceeds in an *invariable* ratio its specific heat under a constant volume; and that, if such be the case with steam, the rises of true temperature produced in it by compression must at least be proportional to those in air, whether they may be exactly equal to them or not. This, to be sure, is very different from the theory of Clement, to which, we presume, fatal objections have been stated in our article EVAPORATION (vol. ix. pp. 425, 426). But since there is no known instance of any other law of repulsion than the reciprocal of the square of the distance, it is most unlikely that the particles of air alone should observe this, and other gaseous particles different laws.

From such considerations we are led to conclude that steam should have the ratio of its specific heats not only constant (as Laplace and Poisson maintain), but the same as in air, and consequently have its temperature raised at the same rate by compression; and, till something else be shown to the contrary, we shall adopt Mr Watt's opinion, which, we presume, few will be disposed to dispute, that the latent heat of steam is the same with the heat which would be evolved or rendered sensible by compressing steam to the density of water. By means of these as data we shall proceed to compute the latent heat of steam in terms of its own specific heat. It has been usual to express it in terms of the specific heat of an equal weight of water at some low temperature; as, for instance, to reckon it equal to 1000 times the specific heat of water. This quantity there is reason to suspect to be a very different thing from the sum of the successive specific heats of water, according to the common graduation, continued up through a range of 1000°; in other words, the latent heat of steam is probably very different from the quantity of heat which would raise the temperature of an equal weight of water up through a range of 1000° on Fahrenheit's scale, though they are usually assumed to be equal.

In conformity, then, with the principles which have been laid down as above, let the specific heat of steam at 212°, or the quantity of heat which it would be necessary to add to raise its temperature 1° under a constant volume at 212°, be represented by the variation for one degree in the logarithm of the temperature counted from $-448°$ on Fahrenheit's scale of an air thermometer; namely, by $\log.(448+213) - \log.(448+212) = \cdot0006576$. Steam having a pressure of one atmosphere at 212°, is, according to M. Gay-Lussac, 1694 times rarer than water at 32°, and, consequently, about 1626 times rarer than water at 212°. Hence, on the principles now adopted, were such steam suddenly compressed to the density of water, or to the 1626th part of its bulk, it would have its true temperature raised above 212° by a quantity proportional to, and which might be represented by, $\frac{1}{3}\log. 1626$; that is, supposing that the specific heat of steam should, like that of air, bear the same ratio to the heat which is evolved or rendered sensible by compression, that $\cdot0006576$ bears to $\frac{1}{3}\log. 1626$ (because $\frac{m-n}{n} = \frac{1}{3}$); and that the heat thus evolved, and which is to raise the temperature of the steam so much under the reduced volume, is equal to the heat which it would have been necessary to have added to the steam before its volume was reduced at all, in order to raise its temperature as much under that original volume unaltered. For we have seen that the *magnitude* of the volume, if constant, makes no difference on the quantity of heat necessary to raise the temperature of a given mass of air through the same range, and that as little does the *intensity* of the pressure if constant. Now $\frac{1}{3}\log. 1626 = 1\cdot0703735$, in which $\cdot0006576$, the above representa-

Hygrometry.

tive of one degree, is contained 1627·7 times; so that 1628° is the latent heat, in terms of the specific heat of the steam itself at 212° under a constant volume. According to MM. Delaroche and Berard, the specific heat of steam, notwithstanding its vastly greater volume, is only ·847 of that of water; but since ·847 refers to steam under a constant pressure, three fourths of it, or ·635, will be the number for steam under a constant volume. Hence the latent heat of steam, in terms of the specific heat of water, should be $1627·7 \times ·635 = 1034°$, which comes very near the usual estimate; but to this we attach little importance, because we see no ground to believe that the specific heat of steam can be so much, if at all, smaller than that of water at the same temperature. Indeed, considering the vague, complicated, and indirect manner in which Delaroche and Berard obtained the number ·847, it is astonishing that other philosophers should ever have adopted it. Were we to suppose the specific heats of steam and water to be equal at 45° (the mean temperature of the water in which Dr Ure condensed the steam in his experiments), the latent heat of steam at 212° would be 1216° in terms of the specific heat of water at 45°, because $\log. (448 + 46) - \log. (448 + 45) = ·00088$, and is contained 1216·3 times in 1·0703735. This, to be sure, rather exceeds the ordinary estimates, which is no great objection to its accuracy; because in the most approved methods hitherto followed for obtaining experimentally the latent heat, there is reason to suspect that some of the steam, in its passage from the boiler or retort, would be so much cooled as to have either attained the liquid form or the state of a cloud before it reached the cold water in which it was to be condensed, a circumstance which would tend to bring out a deficient result, especially if the steam reached the cold water by a horizontal or descending tube, which could not bring back to the boiler any water formed from steam condensed by the way; but it is doubtful if any tube could entirely obviate this, or prevent cloudy vapour from passing over. Besides, the latent heat being generally computed from a slight rise produced by it in the temperature of a large mass of water, it is obvious that a small inaccuracy in measuring such rise may occasion a considerable error in the latent heat; and it has often been alleged that the heat which raises the temperature of water one degree, is far greater than the thousandth part of what would raise it a thousand successive degrees reckoned on the common scale.

But to come nearer our present purpose; since the latent heat of steam, in terms of the specific heat of water, is scarcely a necessary ingredient in the theory of the moist-bulb hygrometer, we shall now compute the latent heat of steam at 32° Fahrenheit, in terms of its own specific heat under a constant volume at that temperature. Steam in a state of saturation at 32° is about 177200 times rarer than water at same temperature, and $\log. (33 + 448) - \log. (32 + 448) = ·0009039$. This, which represents the specific heat, or one degree at 32°, is contained 1935·5 times in $1·74949 = \frac{1}{3} \log. 177200$. Hence the latent heat at 32° is 1935·5. Now, according to the view we have taken of the subject, the latent heat of steam is expressed by the number of times the above numerical value of the specific heat of an equal weight of it at some particular temperature is contained in one third the logarithm of the number of times the steam is rarer than water. But if we wish to express it always in terms of one quantity, as, for instance, in terms of the specific heat of an equal weight of it under a constant volume at 32°, we shall have log. 177200 to log. R. as 1935·5, the latent heat at 32°, to the latent heat of an equal weight of aqueous vapour at a different temperature, and whose rarity, compared with that of water of its own temperature, is R; so that the latent heat, in the terms now specified, will be

$$\frac{1935·5 \log. R}{5·24846} = 368·77 \log. R,$$

which varies as the logarithm of the number of times the steam is rarer than water, as was hinted in the article Evaporation, vol. ix. p. 426. We there noticed, p. 425, an experiment which proves in a very decisive manner, and independently of any thing now stated, that not only the latent, but the total heat in a given mass of steam in a state of saturation must be less at higher temperatures than at lower. Now, both this and the results of our investigation are consistent with, nay afford a very satisfactory reason for, the well-known economy of heat in high-pressure engines; whereas the usually-received theory of Clement, which supposes the latent heat the same at every temperature, is quite incompatible with such economy. Our investigation also leads to a saving of heat in the case of steam used *expansively*, as it is called; but it would here be out of place to go through the computation at length. For some interesting experiments and remarks by Dr Haycraft, on this, which he calls *surcharged* steam, see *Repertory of Patent Inventions*, vol. xii. p. 25.

M. de la Rive's hygrometer.

M. de la Rive some time ago proposed for a hygrometer the following contrivance, which is, in some respects, the counterpart of the one with the moist bulb. A thermometer being dipped in sulphuric acid, and then exposed to the air, absorbs and condenses the aqueous vapour, which, by evolving its latent heat, and imparting it to the acid, raises the temperature of the thermometer. From this increased temperature, and that of the air, M. de la Rive computes the degree of humidity. In this case, the warming effect of the condensed vapour is restrained by the cooling influence of the air and the radiation of surrounding bodies; whereas in the hygrometer with the moist bulb, the cooling effect of evaporation is limited by the warming influence of the air and radiation. But it is only when the vapour is in a state of half saturation, that either the changes of temperature or the effects of radiation are likely to be nearly equal in the two hygrometers. Perhaps, therefore, a careful comparison of the indications of these instruments in other states of the vapour might afford data for estimating how far they are under the influence of radiation, which would tend materially to elucidate their theories.

While the sulphuric-acid hygrometer displays considerable ingenuity, the other instrument is on several accounts so decidedly preferable, that the invention of M. de la Rive is not likely ever to come into general use. Water can more readily be obtained everywhere, and is much more safe and portable, than sulphuric acid. Besides, owing to sulphuric acid freezing at an uncertain or variable temperature, depending on its strength, such an instrument would be apt to give doubtful results at low temperatures. For, whatever be the strength of the acid at first, it will continue to decrease in an uncertain manner on the bulb by gradually absorbing moisture. However, the heat derived from the condensation of the vapour will sometimes be sufficient to keep the acid in a liquid state at a temperature which would freeze it in a close vessel; and whenever it happens that sulphuric acid remains liquid on the bulb of one thermometer, while water is frozen on that of another, a comparison of the two instruments might throw some light on the influence of frost on the temperature of the latter. We presume, therefore, that the most important use likely to be derived from this hygrometer of M. de la Rive, would be to assist in perfecting the theory of the moist-bulb hygrometer; and possibly some other absorbent substances might answer even better for this purpose than sulphuric acid does.

Hygrometer by compression.

Since the quantity of aqueous vapour which can exist in a given volume is independent of the density of the air, it

Hygrometry.

is evident that, when the vapour in the air is in a state of half saturation, we may bring it to complete saturation by injecting additional air into a close vessel till the density is doubled, and doing this either so slowly as not sensibly to warm the air, or to wait a little till the temperature settle. If the vessel is large and of a globular shape, a deposition of moisture should be sensibly produced on its inner surface, so soon as the density gets a very little beyond the double; but with a small vessel, a greater increase of density would be required, because in that case the included mass of vapour would be smaller in proportion to the surface. It would on several accounts be preferable that any vessel for this purpose should be formed of metal with two small openings on opposite sides, closed by bits of glass which would become dim by the deposition of dew on their interior surfaces. Whatever might be the proportion of humidity in the air, it would in all cases be in the inverse ratio of that in which the density was to be increased to produce saturation, and so might be readily had from such a manometer or gauge as is usually employed for showing the pressure, only having a direct in place of an inverse graduation. If a thermometer were included in the vessel, it would need to be cased like that of Dr Hutton's hygrometer, to protect it from the pressure, which, by compressing the bulb, might cause it to show a temperature far above the truth.

Statical hygrometer.

A hygrometer depending on the increase of pressure which additional moisture produces in air not thoroughly damp, will be found described under the article METEOROLOGY; but one depending on the effect which humidity has on the specific gravity of the air might be had by suspending two very light air-tight cylinders of equal dimensions and weight, from the arms of a sensible balance. Thus, if the one cylinder were suspended in a jar containing either a little water, to render the air thoroughly damp, or some drying substance, to render it perfectly dry, the difference in the specific gravities of the exterior and included air would produce a corresponding disturbance in the equilibrium; because the more humid the air, it is the lighter under the same pressure and temperature. The jar would of course need to be closed with a lid, leaving only a small opening for the free motion of a thread or wire suspending the cylinder. The opposite cylinder, too, would need to be suspended in some vessel or cage, only so close as to be a protection from the agitation of the wind.

Since the specific gravity of aqueous vapour is to that of dry air as five to eight, it is evident that when the cylinders, which are to be equal in volume and weight, are both suspended in air of the same temperature and pressure, but differing in humidity, any small weight which, being applied to the more buoyant one, would maintain the equilibrium, must be proportional to the difference in the densities of the aqueous vapour surrounding these two opposite cylinders. So that, if the air around the one were made perfectly dry, the requisite counterpoise would just equal three eighths of the weight of as much aqueous vapour as is contained in a volume of air contiguous to the other cylinder, and equal its bulk. This, however, is not meant to apply to fog or cloudy air, nor are we aware that any other hygrometer does apply to fog. But the same result might be had without any counterpoise, by making the arm of the balance show on a graduated arc the disturbance of equilibrium corresponding to such counterpoise. The apparatus now proposed, though it might be somewhat bulky and expensive, would indicate in the most direct manner, and without regard to temperature or pressure, the actual weight of moisture in the air; and might therefore be of great service in trying and verifying other hygrometers, with the view of obtaining the real values of their indications, and perfecting their theories. It would, in short, possess all the properties which Saussure considered essential to a perfect hygrometer.

Having obtained, by means of such an instrument, g the grains of vapour in a cubic foot of air at the temperature t, the actual force of the vapour will be

$$f = \frac{t + 448}{5658{\cdot}81} \times g.$$

This obviously follows, from what was shown above, in giving the rationale of Leroy's mode of finding the dew-point, namely, that

$$\frac{30}{212 + 448} : \frac{f}{t + 448} :: 257{\cdot}2188 : g.$$

Effect of aqueous vapour on barometric measurements.

It was just observed that the density of aqueous vapour is less than that of dry air at the same temperature and pressure, in the ratio of five to eight. Hence, at the same temperature, the specific gravity of a mixture of air and vapour whose tension is f, is to that of dry air under the same pressure p, as $p - {\cdot}375f$ to p; and therefore, in the mensuration of heights, the weight of a column of air and moisture will have an effect upon the barometer which, *cæteris paribus*, will be less than that of an equally long column of the dry air, in the ratio of $p - {\cdot}375f$ to p. So that, in conformity with the usual principles on which heights are measured, if D be the difference in the logarithms of the corrected pressures at the upper and lower stations, p the mean pressure of the intercepted column of air, t its mean temperature, and f the mean force of its vapour, the height in fathoms will be

$$\frac{p}{p - {\cdot}375f} \times \frac{t + 448}{480} \times 10000\,\mathrm{D}.$$

This includes the reduction of the temperature of the air to 32°; because, under the same mean pressure, the weight of the column of dry air at the temperature t is to its weight at 32° as 480° to $t + 448°$, which is the well-known rate of the expansion of air. We do not, however, mean, that this or any formula is applicable, when the air happens to be foggy or cloudy. Nor would it be of any use here to speculate on, or to attempt to employ, any law according to which the quantity of aqueous vapour may be supposed to vary at different heights, in the form of an independent atmosphere; because the wind and other uncertain vicissitudes of weather derange every thing of this sort, as is evident from the dew-point being found to vary at different heights in a manner which cannot be referred to any definite law which it might be supposed to have followed in perfectly still air.

Formula for the specific gravity of a mixture of air and vapour.

From the above investigation, it is evident that under the pressure p the specific gravity of a mixture of air and vapour whose tension is f, will be to that of dry air of thirty inches pressure at same temperature, as $p - {\cdot}375f$ to 30. So that, if the specific gravity of the dry air of thirty inches pressure at 32° F. be unit, the specific gravity of the mixture at any temperature t will be

$$\frac{p - {\cdot}375f}{30} \times \frac{480}{t + 448} = \frac{16p - 6f}{t + 448}.$$

Professor Daniell has given, in the second edition of his *Essays* (p. 177), an extensive table for finding the specific gravity of a mixture of air and vapour, under a pressure of thirty inches, and for facilitating corrections for the effects of vapour and temperature on barometric measurements; but it requires more trouble to apply it to either of these purposes than the preceding formulæ do; and it is curious that Mr Daniell does not seem aware that the method he follows for correcting measurements, even when aided by that large table, is only suited to a column of air and vapour in a state of saturation, and whose mean pressure is exactly thirty inches; though it rarely happens in the mensuration of heights, that the mean pressure of the air and vapour forming the column is so great. Thus, the force of vapour in the third column of his table being expressed in terms of a pressure of thirty inches as the unit, can of course suit no other; yet in an example on page 183, he applies it as if the mean pressure, 28·77 inches, had been the unit; and no doubt, when the pressure is smaller, it will lead to a more considerable error. A similar objection attaches to the weight or density of vapour in his fourth column; and besides, when he applies it as the "increase of density for weight of vapour," he uses the density of vapour corresponding to the dew-point, which is always greater than the actual density, except when the vapour is in a state of saturation. It is this step in Mr Daniell's method which restricts it to thoroughly damp air; whereas the formulæ we have given above are of general application, only they are not suited to foggy or cloudy air, nor are we aware that any other method is.

Depositions of moisture, &c. from the atmosphere.

We shall now examine some of the more remarkable phenomena resulting from or connected with the deposition of aqueous vapour from the atmosphere. The ingenious Dr James Hutton proposed a theory of rain, which many receive as the true explication of it, viz. that rain is produced by the mixing of different masses of moist air having different temperatures. It is well known from experiment, that the variations in the capacity of air, or more properly of space for moisture, proceed in a higher ratio than the corresponding variations of temperature, as reckoned on the common scales, but still more so with reference to the scale which we deduced above; where it is shown necessarily to follow from admitted principles, that air expands in geometrical progression for equal increments of heat (though this, as we have already noticed, is not precisely the same with the scale which Dr Dalton long ago proposed, and afterwards relinquished). Hence, if the space occupied by the mixture of the different masses of air have either the mean temperature of the whole, or one still lower, its capacity for moisture would come short of the mean, and so a deposition of rain, &c. will ensue, if the air has previously been sufficiently moist. There can be no question that this theory is a possible one; but it would be no easy matter to prove that it is the actual and ordinary mode in which rain is produced. In the *Quarterly Journal of Science* for April 1829, Mr Meikle adduces some reasons countenanced by experiments, which seem to render it very probable that clouds, rain, &c. may often be traced to a nearer and more natural source. The Huttonian theory does not readily explain why rain is more commonly preceded or attended with a falling barometer; for it is as easy to conceive mixtures of air occurring whilst the barometer rises, as when it falls; and the like objection attaches to the electrical theory of rain. Indeed, on many occasions electricity is as serviceable to the moderns as the *occult qualities* were to the ancients; for by referring any difficulty to electricity, we can either evade the trouble of solving it, or the mortification of acknowledging our inability to solve it.

But this prognostic of the falling barometer did not long escape notice after the Torricellian experiment had been made;[1] and the explanation then given, and for long after received, was, that the air, from its rarity, was unable to buoy up or support the denser vapours, and so of course down they came. It was not then known, that, at the same temperature and pressure, moist air, especially if transparent, is lighter than dry. Yet the observers of that period certainly inferred, on very probable grounds, that there existed a connection between the concomitant circumstances of decreasing pressure and depositions of rain, &c. from the atmosphere. They are further to be commended in seeking an explanation in a principle which they supposed to be known; because reason and facts are always preferable to hypotheses. We are far from reckoning their statical explanation to have no share in the phenomena; because the denser the air, the more will it retard or obstruct the descent of minute drops of water or particles of snow, &c.; but the suspension of transparent vapour depends on the temperature alone. For it is now well known, as noticed more particularly under the article Evaporation, that the quantity of vapour contained in a given space is independent of the presence or density of any other elastic fluid with which it is not chemically combined; or that the maximum quantity of vapour which can exist in a given space is the same at the same temperature as it would be did that space contain nothing else. Whenever, therefore, the volume of the same mass of air increases, the capacity of that volume for moisture should increase at the same rate, were the temperature to remain the same; but when air dilates from a diminution of pressure, its temperature always falls, if there be no accession of heat from some other source. A fall in the barometer, however, is not necessarily attended with a reduction of temperature near the earth's surface. On the contrary, the temperature there may often be preserved, or even raised (as we shall afterwards explain), by the intermixture of the higher and lower strata, and by the retention of heat, such as had previously escaped upward by radiation from the earth's surface, but which ceases to do so after the sky is obscured by dense clouds. But where none of these extraneous circumstances interfere, the reduction of temperature properly due to dilatation lessens the capacity of the space so cooled for moisture, far more than the enlargement in bulk increases it; so that, generally speaking, if the air be sufficiently moist, a fall in the barometer, or rarefying the air, should tend to produce clouds, rain, &c.

For example, the volume of a given mass of air will increase about a ninetieth part by being raised through a height of a hundred yards; and the capacity of that volume for moisture would increase in the same ratio did

[1] We are aware that some of the first observers are said to have coupled rain with a rising or high barometer; and indeed there are exceptions. When the wind is shifting from west to east, the barometer generally rises, though followed by copious rain; and, on the other hand, when the wind shifts from east to west, the barometer usually falls, though it remains dry. The motion of the barometer is in such cases to a certain extent connected with the earth's diurnal rotation, and is thus accounted for by Mr Meikle, in the *Edinburgh Phil. Jour.* for December 1827, page 108:—"The curvilinear motion of the wind, describing a circle about the earth, in place of always *lowering* the barometer, as many have supposed, ought frequently to *augment* the pressure of the atmosphere, and consequently to *raise* the barometer. At first sight this may seem paradoxical enough, if not thoroughly absurd; but to solve it we have only to consider, that when the wind is from the east, its diurnal motion round the earth's axis is thereby lessened, its centrifugal force will be of course weakened, and so the air will be more at liberty to gravitate or press freely on the earth's surface. Westerly winds, on the contrary, by conspiring with the diurnal motion, increase the centrifugal force, and diminish the pressure."

The influence of centrifugal force on the pressure will likewise afford a satisfactory reason for hills generally measuring higher by the barometer during wind than during a calm; the air being probably accumulated, or the pressure increased, at the bottom of the hill, by the wind describing almost a straight line, or a curve which is convex downward, while the air is dilated or the pressure diminished at the upper station, by the wind describing over the summit a curve which, compared with the other, is very concave downward. But the difference of centrifugal force at the two stations will have little to do with the diurnal rotation, if the wind has the same velocity and direction at both, though the velocity is more likely to be greater at the summit than below. As for the difference of distance from the earth's centre, it is scarcely worth attending to.

the temperature continue the same. But if the temperature lost one degree, the capacity for moisture would be thereby diminished about a thirtieth; and therefore, upon the whole, aqueous vapour in a state of saturation would have about its forty-fifth part condensed into water by being raised a hundred yards, namely, a thirtieth minus a ninetieth. However, for reasons given above, and to be farther illustrated by and by, it is more likely that the temperature of an ascending current of air will often lose 1°·5 F. or even more, by gaining an elevation of a hundred yards, which would lessen the capacity for vapour about one twentieth. Hence, a rise of a hundred yards would condense about a twenty-sixth part of the vapour, viz. the excess of a twentieth over a ninetieth.

Experiment illustrating the theory of rain, &c.

Such at least would be the result, calculating from the foregoing principles; but the following simple experiment affords a more direct proof that sufficient rarefaction will always change common undried air into a cloud. Connect a small glass flask, containing the ordinary air, with the receiver of an air-pump, by means of an intervening stop-cock. Exhaust the receiver with the cock shut; then looking attentively at the flask, open it suddenly into the receiver, by turning the stop-cock, when a momentary mistiness will be perceived in the flask, which is aqueous vapour condensed into a cloud by the cold produced by the rarefaction. The cloud is here formed under peculiar disadvantages, being everywhere surrounded at so short a distance by a warmer surface throwing in heat upon it, and especially by a vitreous surface which is known to radiate powerfully. But a cloud which is visible in so small a volume would be pretty dense on the large scale. We have never tried this experiment without succeeding; but we believe it may fail when the air contains little moisture, if the receiver be not large compared with the flask, or if the connecting stop-cock have a very narrow bore. It is, however, rare for the external air, in a state of free circulation, to contain so little as a third of the total vapour which could exist in it at the actual temperature.

Since both modes of reasoning lead to the same results, we presume enough has now been said to warrant us to conclude, that when air ascends sufficiently in the atmosphere, it must, from being cooled by dilating, constitute a cloud, or, if moist enough, produce rain, &c. For example, if a current of air traverse the ocean till it becomes very moist; and then, if, on arriving at the shore, this current have to rise higher as the land rises, we have at once the reason why rain so frequently commences nearer the sea, and extends thence forward with the wind,—why more elevated situations are more liable to rain,—and why a wind from the land is more rarely attended with rain on its approaching the shore. But there is reason to think that a stream of air which has been gradually elevated by traversing a rising ground, does not always descend again where the surface declines, but, on the contrary, may continue for some time at that height, or, from the upward force it has already acquired, may even rise higher. In this manner it may deposit rain while rolling far above the tranquil plain, as well as when contending with the asperities of the more elevated surface; especially since the humidity, after being condensed, will be borne along with the current, taking some time to force its way down through the air, and the more so as the air is more dense. If the space over which the raining current passes be not saturated with moisture, the air may revaporize a part or the whole of the rain descending in it. This is no doubt the way in which clouds seem suspended in the air, or even at rest in the wind, though, in fact, they may be falling, and changing into transparent vapour, so as to float on unseen in the wind beneath; whilst their place is continually supplied by the successive condensation of other vapour arriving with the current, and which, in its turn, is revaporized or swept away by the wind. Much in the same way clouds are apparently stationed over elevated peaks, or even over large portions of hills; while the fact is, that their particles are moving onward, and others coming in their stead. The apparent motions of clouds may therefore differ so much from the true as to afford a most fallacious measure of the velocity of the wind.

Theory of mountain-caps.

The circumstance of clouds frequenting hills, or apparently moving towards them, will admit of a similar explanation, without the aid of an imaginary force residing in hills for the express purpose of attracting clouds, rain, &c. The notion that mountain-caps, or clouds hovering about the tops of hills, are produced by the cooling influence of the summit, does not appear to be better founded; because such phenomena frequently occur when the air is considerably colder than the surface of the hill, though they may not continue long of very different temperatures. But were the cloud really owing to the colder temperature of the summit, it would not only touch, but be densest next the surface of the hill, wetting it profusely; whereas the cloud is often observed to be several feet, or many yards, clear of the hill, and the surface as dry at least as that of the surrounding country; a clear proof that the hill is not colder than the cloud. A more natural explanation, we presume, is, that the cloud called the mountain-cap is formed in that part of a current of moist air which is sufficiently cooled by the rarefaction attending its sudden increase of elevation in ascending and rolling over the summit; and that this current will regain its transparency so soon as it afterwards passes on to where it either absorbs as much heat, or acquires an increase of pressure sufficient to restore its former temperature. The reason why the cloud is frequently observed to keep clear of the summit for a considerable time, especially during a brisk wind, is, that the centrifugal force due to the curvature of the current over the hill carries it clear of the summit, and the intervening arched space is left to be occupied by comparatively still air, into which the air recently cooled by rarefaction scarcely enters; and by this means the higher temperature of the summit is preserved for some time. In the same way it often happens, that whilst a storm acts with fury on the face of a precipice, a person on the summit only hears the sound, and feels himself as in a calm; the arched current, with its copious load of rain or hail, being carried clear of the summit by the centrifugal force, while the intermediate space is left almost free from wind, hail, or rain. Since caps rarely occur on hills of moderate height, except when the air is pretty moist, they are not unfrequently precursors of rain.

Much in the same way as in the case of the mountain-cap, may the origin of the cloud called the *cumulus* be traced, especially by means of its horizontal base, to the dilatation of air. Such a cloud may be situated partly in an ascending portion of a current of moist air, and partly in a descending portion; or it may sometimes occupy the most elevated part of an arched-like sweep of the current. Whenever the air reaches the requisite elevation, it will become opaque, but will regain its transparency so soon as it descends again sufficiently to have its temperature restored by increase of pressure. The opacity should terminate underneath nearly all at the same level, or in a horizontal plane, if the heat and moisture have been uniformly or proportionally distributed through the air of the current. When the distribution has been unequal, the base will of course be uneven, or may deviate more or less from a horizontal plane. Perhaps some other modifications of clouds might be accounted for on similar principles. We may farther observe, that clouds, when seen in profile, especially the several parts of the cirrus, when changing into cirro-cumulus, generally appear as if leaning forward like shrubs in the direction in which the wind moves; and longer pieces of cloud are commonly lower in the rear than in front.

Gradation of temperature in the atmosphere.

It is evident that moisture which has ascended in the form of transparent vapour, and descended again as rain, snow, &c. must have left its latent heat above. But much heat no doubt moves upward, from its natural propensity to render the atmosphere of one temperature throughout its whole height, and from the tendency of warmer air to rise above the colder. There is therefore good reason for concluding, that air which has just been suddenly elevated and dilated should be thereby reduced to a much lower temperature than what obtains in air which has remained at that elevation for some considerable time, receiving heat from below, from the sun, or other sources. This is both in accordance with direct observation, and with the conclusions at which we arrived when investigating the relations of air to heat. For the entire fall of temperature properly due to dilatation, as expressed by either of the formulæ given above, viz.

$$(\tau + 248)\left[\left(\frac{\varrho}{\varrho'}\right)^{\frac{1}{3}} - 1\right], \text{ or } (\tau + 448)\left[\left(\frac{p}{p'}\right)^{\frac{1}{4}} - 1\right]$$

far exceeds a reduction of one degree for every 100 yards of ascent. In Gay-Lussac's famous ascent, the pressure was reduced in the ratio of ·432 to 1 at a height of 7600 yards, and the temperature fell 72°·54, or from 87°·44 to 14°·9; so that the density was very nearly halved. With these data, the first formula gives $(87{\cdot}44 + 448)\left[\left(\frac{1}{2}\right)^{\frac{1}{3}} - 1\right] = 110^\circ{\cdot}46$ for the fall of temperature; but the second gives about 9° less, or $(535{\cdot}44)\left[({\cdot}432)^{\frac{1}{4}} - 1\right] = 101^\circ{\cdot}35$; and so it ought, because in Gay-Lussac's ascent the cube of the pressure decreased more slowly than in the ratio of the fourth power of the density. However, there is reason to think that when a strong wind runs up a steep acclivity, the temperature would be found to decrease very nearly in such a manner that the cube of the pressure would, as in these formulæ, vary as the fourth power of the density. To make a proper trial of this, it would need to be done on air which is free from any tendency to deposit moisture, as also when the surface of the acclivity is dry, and completely shaded by elevated clouds from the sun and the aspect of a clear sky, in order that the temperature of the air and surface might everywhere correspond. As the wind is more likely to escape past the sides of an elevated peak than go right over its top, an acclivity proper for this purpose would need to be of such an extent that the temperatures and pressures could be observed in parts of the currents where we were sure the air was making no lateral escape. Calculating then from the second formula, it would follow, that when such a current ascends to where the pressure is reduced in the ratio of ·432 to 1, the temperature should fall from 87°·44 to — 13°·91, or 101°·35, which, being greater than 72°·54, shows that, in this case, the density would not be reduced quite to the half.

The experiment already described for producing the cloud in the flask shows that if an equal weight of air in the upper regions did not contain far more heat than in the lower, the sky would be perpetually obscured with clouds. This is further illustrated by the circumstance, that when the atmosphere is much agitated and intermixed to a great height, it becomes obscured above, no doubt from the dilatation rendering the recently ascended air colder there than corresponds to the constituent temperature of the vapour which it had brought along with it, while the air beneath, which has recently descended, being warmed to or above the dew-point of its vapour, by compression becomes quite transparent, though previously it might have been opaque. In such cases the clouds often present a deep-blue colour. However, it is long since Dr Dalton (*Chemical Philosophy*, vol. i. p. 123) proposed the hypothesis that heat was diffused equally, or in the same proportion as the density of the air, throughout the whole height of the atmosphere; in other words, that a given weight of air anywhere in a perpendicular column contained the same quantity of heat. In this he was followed by several eminent philosophers, though it is quite incompatible with the facts now stated, and would, besides, require the temperature to decrease so rapidly with the elevation, that aqueous vapour, by its superior elasticity, would always shoot up through the air to where it would be condensed by the cold into a cloud, keeping the sky perpetually obscured, which is contrary to observation.

Hygrometry.

Dr Dalton's hypothesis.

It has become a common maxim, that dry air is less transparent than moist; the latter of course being free from fog or cloud. If it is meant that mere dryness impairs the transparency, we should be very apt to question such doctrine, though we do not dispute that the atmosphere is less transparent in very droughty weather. The reason of this we presume to be, that much solid matter is then diffused through the atmosphere in the form of dust or smoke, a great part of which, had it been sufficiently moist, would have been too heavy to float in the air; and some of the remainder, had it been more humid, might have assumed the gaseous form, so as to be transparent.

The temperature at the tops of mountains is generally found to be lower than that of air at the same height over the plains; and a probable reason for it is, that mountains, besides having their temperatures reduced by radiation, are apt to be further cooled by and enveloped in recently dilated ascending currents of air rolling over them. But here again it should be remembered, that our knowledge of the temperature at great heights over the plains has for the most part been derived from a few ascents in balloons, undertaken during the day, and only in very serene and mild weather, when there was scarcely any interchange going on between the air of the different strata. Nothing is known of the decrease of temperature over the plains in a coarse winter night. The same remarks apply in a great measure to ascents on very high mountains; so that in all probability the mean decrease of temperature in the atmosphere has hitherto been greatly underrated. Snow-clad mountains are, besides, cooled, particularly in very dry weather, by the evaporation from the snow; and we may remark, by the by, that at the same temperature, dry air is, for the above reason, less efficacious in melting snow than moist. Because the moist air, in place of spending its heat to form vapour, does, in consequence of its touching a colder body, part with a portion of the latent heat of the vapour it already contained, which must greatly aid in liquefying the snow. The melting of snow therefore does not depend solely on the temperature of the wind, but likewise upon its being previously charged with moisture. Besides, when dry air passes over snow on a high mountain, the evaporation, and consequently the reduction of temperature, will be greatly promoted by the diminished pressure which obtains at such heights. This may help to explain why *snow-winds*, as they are called, should be found so intensely cold; for the mere circumstance of wind having passed over a cold mountain is not a sufficient reason why it should be cold after its descent. But we may here observe by the by, that the reason why snow at great elevations is so little affected by the action of the sun's rays, is, that the rarity of the air induces such a tendency to evaporation, that the moisture evaporates just as fast as it melts, and in this way expends by far the greater part of the sun's heat on the formation of vapour. For since the vaporization of water consumes about seven times as much heat as the melting does, it follows that the heat spent in both melting and evaporating an ounce of snow, would melt no less than eight ounces without evaporation.

Decre[ase] of tem[pe]rature [pro]bably [un]derrat[ed].

Hylozoists.

The explanation which we proposed above of the phenomena of clouds seeming stationary in the wind, appears to be applicable to water-spouts. We readily allow that the ascent of the water in them has been long accounted for in a very rational way, which is briefly this: The collision of currents of air from different quarters produces a whirlwind; the air near the axis of rotation is rarefied by the centrifugal force; and the pressure on the spot under this attenuated air is necessarily diminished. Of course, when a whirlwind occurs on the sea, a lake, or a river, the water rises in the axis of rotation, on the same principle as in the common pump. But the rarefied air itself ascends in virtue of its levity. Its place is supplied by the concourse of the heavier adjacent air, which being rarefied in its turn, ascends; and in this manner an upward current of air is produced, which aids the ascent of the water. Thus far the explanation is very satisfactory. The other principal part of the phenomenon, the apparent descent of a dense stem from the clouds, nearly over the spot where the water rises, has been ascribed to electricity. But this we cannot help regarding as an evasion savouring of occult qualities, rather than an explanation. It seems nearly allied to the notion that hills attract clouds. The column which apparently descends from the clouds (for any descent is altogether illusory till water actually fall) may be accounted for in the same way as the mountain-cap, viz. that it is aqueous vapour condensed by the cold due to the rarefaction which is occasioned both by the whirling motion of the air and by its rapid ascent. The more swift the rotation, the greater obviously will be the rarefaction and cold; and of course the lower down in the axis or stem will the condensation of moisture extend. The sound and flashes of light seem to be thunder and lightning in miniature, according to a theory which will presently be explained. In attending to this and other atmospherical phenomena, most people are embarrassed with a preconception which is not easily overcome, namely, that clouds are solids, or something more substantial than the air in which they are formed.

Theory of thunder and lightning.

We have been long of opinion that the usually received theory of thunder and lightning, as well as that of rain, is unnecessarily complicated and far-fetched, and we therefore regard the following as a more natural and simple one. Volta supposed that bodies, while passing into the gaseous form, absorb electricity, which they emit again on being condensed. Several objections have been made to this, particularly by M. Pouillet; but as they rest in a great measure on the assumption that we possess perfect electrometers, and that experiments made with them are free from every source of fallacy, such objections have not, we think, disproved the more probable opinion of Volta, which has been adopted by several eminent philosophers, who maintain that the electricity emitted by the condensation of steam is always positive. Thunder is unknown in the polar regions, and rarely occurs anywhere in cold weather; from which it appears that thunder does not take place in air incapable of containing much moisture, as is farther confirmed by its being ordinarily produced in a dense cloud. The mode of explaining thunder, &c. which we would therefore prefer, is, that when a large mass of warm and damp air is suddenly moved upwards, it dilates, is cooled, and deposits a considerable share of its moisture, which, in laying aside the gaseous form, parts with positive electricity so suddenly, and in such quantity, that the air is unable to conduct or convey it away in an imperceptible form; and thus the cloud, at the moment of its formation, may in ordinary language be said to emit lightning. The sound may be partly a tremor which the air sustains at the moment the pressure is relaxed by the vapour suddenly losing the elastic form, and may be partly a tremor due to an effort of the electricity to make its escape from the cloud. The thunder and lightning which sometimes attend the condensations of large volumes of steam emitted by volcanoes, are favourable to this theory, as are likewise the noise and lightning of the water-spout already mentioned, if not some parts of the northern lights. A theory very similar to this, though more in detail, was not long ago proposed to the Royal Society, by the Rev. G. Fisher; but the same thing had been previously suggested by Mr Meikle, in the *Quarterly Journal of Science* for April 1829.

Several important matters connected with this subject we have not felt warranted to introduce, on account of their not being yet determined by sufficiently extensive observations; such as the maximum, mean, and minimum dew-points for different hours of the day, for different seasons of the year, for different heights in the atmosphere, and in different countries. We now take leave of the subject by referring again to the various works already cited here, and in the article EVAPORATION; as also to the *Reports of the British Association*, particularly the very excellent one by Professor Forbes on Meteorology. See also the articles ATMOSPHERE, AURORA-BOREALIS, CLIMATE, CLOUD, DEW, &c. in this work. (E. E. E.)

HYGROSCOPE. The same with HYGROMETER.

HYLOZOISTS, formed from ὕλη, *matter*, and ζωη, *life*, the name of a sect of atheists amongst the ancient Greek philosophers, who maintained that matter had some natural perception, strictly so called, without animal sensation or reflection; but that this imperfect life occasioned that organization whence sensation and reflection afterwards arose. Of these, some held that there was only one life, which they called a plastic nature, presiding regularly and invariably over the whole corporeal universe, represented by them as a kind of large plant or vegetable. These were called the cosmoplastic and stoical atheists, because the Stoics believed such a nature, though many of them supposed it to be the instrument of the Deity. But others thought that every particle of matter was endowed with life, and represented the mundane system as depending upon a certain mixture of chance and plastic or orderly nature united together. These were called the *Stratonici*, from Strato Lampsacenus, a disciple of Theophrastus, called also Physicus (Cicero *De Nat. Deor.* lib. i. cap. 13), who was first a celebrated Peripatetic, and afterwards formed this new system of atheism for himself. Besides these two forms of atheism, some of the ancient philosophers were Hylopathians, or Anaximandrians, deriving all things from dead and stupid matter, in the way of qualities and forms, generative and corruptible; and others again adopted the atomical or Democritical system, by which the production of the universe is ascribed to atoms and figures.

HYMENÆAL, something belonging to marriage, and so called from HYMEN.

Hymenæus.

HYMENÆUS, or HYMEN, the god of marriage amongst the Greeks, the son of Apollo and Calliope, or of Bacchus and Venus. Others have thought that he was an Athenian youth, who disguised himself in female attire, that he might accompany his mistress to Eleusis, when she went with others to offer up sacrifice. They were seized by pirates and carried to sea; but Hymenæus encouraged his female companions, and with their assistance put the pirates to death. The Athenians were so pleased at the rescue of their friends, that they allowed him to marry the lady of his affection, who had been refused to him till that time. Hymenæus enjoyed so much happiness from his marriage, that the Athenians invoked him solemnly at their nuptials, as the Romans did Thalassius.

He is represented by the poets as crowned with flowers, particularly with marjoram, having a *flammeum* (veil of a flame colour) on his head, and a torch in his hand. (Serv. *Ecl.* viii. 30; *Æn.* iv. 99, 127; Donat. *Ter. Adel.* v. 7, 6; Lactan. *Stat. Theb.* iii. 283.)

HYMENOPTERA, derived from ὑμην, *membrane*, and πτερον, *wing*, in the Linnæan system of natural history, is an order of insects having four membranaceous wings, whilst the tails of the females are furnished with stings, which in some are used for instilling poison, and in others for merely piercing the bark and leaves of trees, and the bodies of other animals, in which they deposit their eggs.

HYMETTUS, in *Ancient Geography*, a mountain of Attica, near Athens, celebrated for its marble quarries, and for its excellent honey. Pliny says that the orator Crassus was the first who had columns executed from the marble of Hymettus.

HYMN, a song or ode in honour of God, or a poem, proper to be sung, composed in honour of some deity. The word is Greek, ὑμνος, *hymn*, formed from the verb ὑδω, *celebro*, I celebrate. Isidore remarks on this word, that *hymn* is properly a song of joy, full of the praises of God, by which, according to him, it is distinguished from *threna*, which is a mourning song, full of lamentation.

St Hilary, bishop of Poictiers, is said to have been the first who composed hymns to be sung in churches; and he was followed by St Ambrose. Most of those contained in the Roman breviary were composed by Prudentius. They have been translated into French verse by Messieurs de Port-Royal. In the Greek liturgy there are four kinds of hymns; but the word is not employed in the sense of a praise offered in verse, but simply of a laud or praise. The angelic hymn, or *Gloria in excelsis*, is of the first kind; the trisagion is of the second; the Cherubic hymn is of the third; and the hymn of *victory* and *triumph*, called ἐπινικιος, the last.

The hymns or odes of the ancients generally consisted of three sorts of stanzas; one of which, called *strophe*, was sung by the band as they walked from east to west; another, called *antistrophe*, was performed as they returned from west to east; and the third part, or *epode*, was sung before the altar. The Jewish hymns were accompanied with trumpets, drums, and cymbals, to assist the voices of the Levites and the people.

HYPALLAGE, amongst grammarians, a species of hyperbaton, consisting in a mutual permutation of one case for another. Thus Virgil says, *Dare classibus austros*, for *dare classes austris;* and again, *Nec dum illis labra admovi*, for *nec dum illa labris admovi.*

HYPANTE, or Hyperpante, a name given by the Greeks to the feast of the presentation of Jesus in the temple. This word, which signifies *lowly* or *humble meeting*, was given to this feast from the meeting of old Simeon and Anna the prophetess in the temple, when Jesus was brought thither.

HYPATIA, a learned and beautiful lady of antiquity, the daughter of Theon, a celebrated philosopher and mathematician, and president of the Alexandrian school, was born at Alexandria about the end of the fourth century. Her father, encouraged by her extraordinary genius, had her not only educated in all the ordinary accomplishments of her sex, but instructed in the most abstruse sciences. In philosophy, geometry, and astronomy she made such progress, that she was justly accounted the most learned person of her time. At length she was thought worthy to succeed her father in the government of the school of Alexandria, and to teach from that chair where Ammonius, Hierocles, and many other great men, had taught before; and this at a time too when men of great learning abounded both at Alexandria and in many other parts of the Roman empire. Her fame was so extensive, and her worth so universally acknowledged, that her prelections were attended by a crowded auditory. One cannot represent to himself, without pleasure, the flower of all the youth of Europe, Asia, and Africa, sitting at the feet of a very beautiful woman (for such we are assured Hypatia was), all greedily imbibing instruction from her mouth, and many of them, doubtless, love from her eyes; though we are not sure that she ever listened to any solicitations, since Suidas, who talks of her marriage with Isiodorus, at the same time relates, not very consistently, that she died a maid.

Her scholars were as eminent as they were numerous. One of them was the celebrated Synesius, who afterwards became bishop of Ptolemais. This ancient Christian Platonist everywhere bears the strongest as well as the most grateful testimony to the virtue of his tutoress; and never mentions her without the most profound respect, and sometimes in terms of affection little short of adoration. But it was not Synesius and the disciples of the Alexandrian school alone who admired Hypatia for her virtue and learning. Never was woman more caressed by the public, and yet never woman maintained a more unspotted character. She was held as an oracle for her wisdom, which made her be consulted by the magistrates in all important cases; and this frequently drew her into the greatest intercourse with men, without the least censure of her manners. In a word, when Nicephorus intended to pay the highest compliment to the Princess Eudocia, he thought he could not do it better than by calling her another Hypatia.

Whilst Hypatia thus reigned as the brightest ornament of Alexandria, Orestes governed the same place for the Emperor Theodosius, and Cyril was bishop or patriarch. Orestes having received a liberal education, could not but admire Hypatia; and, as a wise governor, he frequently consulted her. But this, together with an aversion which Cyril entertained to Orestes, proved fatal to the lady. One day about five hundred monks having assembled, attacked the governor, and would have killed him, had he not been rescued by the townsmen; and the respect which Orestes entertained for Hypatia causing her to be traduced amongst the Christian multitude, they dragged her from her chair, tore her in pieces, and burned her limbs. Cyril is more than suspected of having fomented this tragedy. Cave indeed endeavours to remove from the patriarch the imputation of so horrid an action, and lays it upon the Alexandrian mob in general, whom he calls *levissimum hominum genus*, a very fickle, inconstant race. But though Cyril should be allowed to have been neither the perpetrator, nor even the contriver, of the murder, yet it is strongly suspected that he did not discountenance it in the manner he ought to have done; and this suspicion is greatly confirmed by reflecting that he was so far from blaming the outrage committed by the monks upon Orestes, that he afterwards received the dead body of Ammonius, one of the most forward in that outrage, who had grievously wounded the governor, and who was justly punished with death.

HYPER, a Greek preposition frequently used in composition, where it denotes excess; its literal signification being *above* or *beyond*.

HYPERBATON, in *Grammar*, a figurative construction, inverting the natural and proper order of words and sentences. The several species of the hyperbaton are, the anastrophe, the hysteron-proteron, the hypallage, synchysis, tmesis, parenthesis, and the hyperbaton strictly so called.

Hyperbaton, strictly so called, is a long retention of the verb which completes the sentence, as in the following example from Virgil:

> Interea Reges: ingenti mole Latinus
> Quadrijugo vehitur curru, cui tempora circum
> Aurati bis sex radii fulgentia cingunt,
> Solis avi specimen: bigis it Turnus in albis,
> Bina manu lato crispans hastilia ferro:
> Hinc Pater Æneas, Romanæ stirpis origo,
> Sidereo flagrans clypeo et cœlestibus armis;
> Et juxta Ascanius, magnæ spes altera Romæ:
> Procedunt castris.

HYPERBOLA, a curve formed by cutting a cone in a direction parallel to its axis. See CONIC SECTIONS.

HYPERBOLA Deficient is a curve having only one asymptote, though two hyperbolic legs running out infinitely by the side of the asymptote, but contrariwise.

HYPERBOLE, in *Rhetoric*, a figure by which the truth and reality of things are either enlarged or diminished, exaggerated or depreciated.

An object uncommon in respect of size, that is either very great of its kind or very little, strikes us with surprise; and this emotion forces upon the mind a momentary conviction that the object is greater or less than it is in reality. The same effect precisely attends figurative grandeur or littleness; and hence arises the hyperbole, which expresses this momentary conviction. A writer, taking advantage of this natural delusion, enriches his description greatly by the hyperbole; and the reader, even in his coolest moments, relishes this figure, being sensible that it is the operation of nature upon a warm fancy.

It cannot have escaped observation, that a writer is generally more successful in magnifying by a hyperbole than in diminishing. The reason is, that a minute object contracts the mind, and fetters its powers of imagination; but the mind, dilated and inflamed with a grand object, moulds with great facility objects for its gratification. Longinus, treating a diminishing hyperbole, cites the following ludicrous thought from a comic poet: "He was owner of a bit of ground not larger than a Lacedæmonian letter." But, for the reason now given, the hyperbole has far the greater force in magnifying objects.

Quintilian holds the hyperbole to be a natural figure: "For," says he, "not contented with truth, we naturally incline to augment or diminish beyond it; and for this reason the hyperbole is familiar even amongst the vulgar and illiterate;" and he adds, very justly, "that the hyperbole is then proper, when the object of itself exceeds the common measure."

HYPERBOREAN, in *Ancient Geography*, a term applied to those people and places which were to the northward of the Scythians. The ancients had but very little acquaintance with the Hyperborean regions; and all that they tell us respecting them is doubtful, and much of it positively false. According to Diodorus Siculus, the Hyperboreans were so called by reason that they dwelt beyond the wind Boreas; ὑπερ signifying above or beyond, and Βορεας, *Boreas*, the north wind. This etymology is natural and plausible, notwithstanding all that has been said against it by Rudbeck, who contends that the word is Gothic, and signifies *nobility*. Herodotus doubts whether or not there were any such nations as the Hyperboreans. Strabo, who professes to believe that there were, does not take *hyperborean* to signify *beyond Boreas* or the north, as Herodotus understood it. The preposition ὑπερ, in this case, he supposes only to help to form a superlative, so that *hyperborean*, on his principles, means no more than *most northern*; from which it appears that the ancients themselves scarcely knew what the name meant. Several of our modern geographers, as Hoffman, Cellarius, and others, have placed the Hyperboreans in the northern parts of the European continent, that is, amongst the Siberians and Samoieds. According to them, the Hyperboreans of the ancients were those in general who lived farthest to the north. The Hyperboreans of our days are those Russians who inhabit the country between the Volga and the White Sea. According to Cluvier, the name Celts was synonymous with that of Hyperboreans.

HYPERCATALECTIC, in the Greek and Latin poetry, is applied to a verse that has one or two syllables too much, or beyond the regular and just measure; as,

> Musæ sorores sunt Minervæ:

Also,

> Musæ sorores Palladis lugent.

HYPERCRITIC, an over-rigid censor or critic; one who will let nothing pass, but animadverts severely on the slightest fault. The word is compounded of ὑπερ, *super*, over, above, beyond; and κριτικος, from κριτης, *judex*, a verbal form of κρινω, *judico*, I judge.

HYPERDULIA, in the Roman Catholic theology, is the worship rendered to the holy virgin. The word is Greek, ὑπερδυλεια, composed of ὑπερ, *above*, and δυλεια, *worship, service*. The worship offered to saints is called *dulia*; and that to the mother of God, *hyperdulia*, as being superior to the former.

HYPERIDES, a celebrated orator of Athens, was son of Glaucippus, respecting whose private history we are able to collect a few facts from the Orations of Demosthenes and the Bibliotheca of Photius (p. 1479). The exact date of his birth is not known; but he was put to death B. C. 322, the same year in which Demosthenes poisoned himself. He studied philosophy under Plato, but not along with Isocrates, as is stated by Photius; for Isocrates was born B. C. 436, and must have been far advanced in years when Hyperides was born. Hyperides adopted the same line of politics as Demosthenes, and opposed with great perseverance the proceedings of Philip of Macedon. That monarch, dreading lest the Athenians should be inclined to throw obstacles in the way of his projects, took into his pay many of the chief orators of Athens, at the head of whom was Æschines. Demosthenes, who was chief of the opposite party, recommended an alliance with the king of Persia, whose dominions were equally threatened by Philip; and it would appear that Hyperides and Ephialtes were employed in a secret negotiation for this purpose. When Eubœa was threatened with invasion by Philip, Hyperides, finding that the Athenians were wasting the time in vain debates, had sufficient influence with the richer citizens to prevail upon them to fit out a fleet of forty triremes, two of which he equipped at his own expense. He was employed under Phocion, in the expedition which was sent to the assistance of Byzantium, when it was besieged by Philip, B. C. 339; and after the battle of Chæronea, B. C. 338, it was through his energetic means that Athens obtained an honourable peace. He was afterwards accused by Aristogeiton of having violated at this period all the laws of the republic; but in his defence he made that celebrated reply, that he had been dazzled by the arms of the Macedonians, and that it was not he, but the battle of Chæronea, which had caused the decree to pass of which he was now accused. He was one of the few whose lives were demanded of the Athenians by Alexander, after the destruction of Thebes, B. C. 335; but it appears that Demades contrived to appease the wrath of the prince, and Hyperides was allowed to remain in his country. He seems to have been honourably distinguished from the orators of his time by an entire freedom from avarice; he resisted the bribes of Harpalus, and was therefore employed to prosecute those who had allowed themselves to be corrupted; he was also one of the accusers of Demosthenes. The troops, however, which Harpalus had brought with him he advised the Athenians to retain; and by means of these, upon the death of Alexander, B C. 323, they were able to commence the Lamian war. Leosthenes the general fell, with many of his troops; and the funeral oration which was pronounced over them by Hyperides was considered by the ancients as one of the most beautiful of its kind. After the defeat of the Greeks, Hyperides was banished from Athens; and having retired to Ægina, was there reconciled to Demosthenes. Being pursued by the Macedonians, he fled to the Temple of Neptune at Hermina, and he was there seized by Archias, who carried him to Corinth, where Antipater then was. Being subjected to torture, some say that he bit off his tongue, that he might not be induced to betray the secrets of his country; whilst others assert that it was cut out by order of Antipater, and that he was then put to death, B. C. 322. Cicero places him immediately after Demosthenes as an orator. There were fifty-two orations of his extant in the time of Photius, and twenty-five others which Photius did not consider as genuine. None of his works have been preserved.

HYPERMNESTRA, in fabulous history, one of the fifty daughters of Danaus, king of Argos. She alone refused to obey the cruel order which Danaus had given to all his daughters, to murder their husbands the first night of their marriage; and therefore saved the life of Lynceus, after she had made him promise not to violate her virginity. Danaus, enraged at her disobedience, confined her closely in prison, whence Lynceus delivered her some time afterwards.

HYPHEN, an accent or character in grammar, implying that two words are to be joined, or connected into one compound word, and marked thus -; as *pre-established*, *five-leaved*, and the like. Hyphens also serve to connect the syllables of such words as are divided by the end of the line.

HYPNOTIC, in the *Materia Medica*, such medicines as in any way produce sleep, whether called *narcotics*, *hypnotics*, *opiates*, or *soporifics*.

HYPO, a Greek particle, retained in the composition of different words borrowed from that language, and literally denoting *under*, *beneath*. In this sense it stands opposed to ὑπερ, *supra*, above.

HYPOBOLE, or Subjection (from ὑπο, and βαλλω, *I cast*), in *Rhetoric*, a figure which is so called because several things are mentioned which seem to make for the contrary side, and each of them is refuted in order. This figure, when complete, consists of three parts; a proposition, an enumeration of particulars with the answers to these, and a conclusion.

HYPOCATHARSIS (compounded of ὑπο, *under*, and καθαιρω, *I purge*), in *Medicine*, a too faint or feeble purgation.

HYPOCAUSTUM, amongst the Greeks and Romans, a subterraneous place, where there was a furnace to heat the baths. The word is Greek, formed from the preposition ὑπο, *under*, and the verb καιω, *to burn*. Amongst the moderns, the *hypocaustum* is that place where the fire is kept which warms a stove or hot-house.

HYPOCHONDRIAC Passion, a disease in men, similar to the hysterical affection in women.

HYPOCRISY, ὑποκρισις, denotes dissimulation with regard to the moral or religious character. In other words, it signifies one who feigns to be what he is not; and it is generally applied to those who assume the appearances of virtue or religion, without in reality having any thing of either.

HYPOGÆUM, ὑπογαιον, formed from ὑπο, *under*, and γαια, *earth*, in the ancient architecture, is a name common to all the parts of a building which are under ground; as the cellar, butteries, and such like places. The term *hypogæum* was used by the Greeks and Romans for subterraneous tombs in which they buried their dead.

Hypogæum, ὑπογαιον, in *Astrology*, is a name given to the celestial houses which are below the horizon; especially the *imum cœli*, or bottom of heaven.

HYPOGASTRIC, an appellation given to the internal branch of the iliac artery.

HYPOGLOTTIS, or Hypoglossis, composed of ὑπο, *under*, and γλωττα, *tongue*, in *Anatomy*, is a name given to two glands of the tongue. There are four large glands of the tongue; two of them, called *hypoglottides*, are situated under it, near the *venæ ranulares*, one on each side of the tongue. They serve to secrete a kind of serous matter of the nature of saliva, which is discharged into the mouth by little ducts near the gums.

Hypoglottis, or *Hypoglossis*, in *Medicine*, denotes an inflammation or ulceration under the tongue, called also *ranula*.

HYPOPYON, in *Medicine*, a collection of purulent matter under the corner of the eye.

HYPOSCENIUM, in *Antiquity*, a partition under the pulpit or logeum of the Greek theatre, appointed for the music.

HYPOSTASIS, a Greek term, literally signifying *substance*, or *subsistence*, and used in theology for *person*. The word is Greek, ὑποστασις, compounded of ὑπο, *sub*, under, and ἱστημι, *sto*, *existo*, I stand, I exist; as if we were to say *subsistentia*. Thus we hold that there is but one nature or essence in God, but three *hypostases* or persons. The term *hypostasis* is of a very ancient standing in the church. St Cyril repeats it several times, as also the phrase "union according to hypostasis." The first time it occurs is in a letter from that father to Nestorius, where he uses it instead of προσωπον, the word we commonly render *person*, which did not seem expressive enough. "The philosophers," says St Cyril, "have allowed three *hypostases*. They have extended the divinity to three *hypostases*; they have even sometimes used the word *trinity*; and nothing was wanting but to have admitted the consubstantiality of the three *hypostases*, to show the unity of the divine nature, exclusively of all triplicity in respect of distinction of nature, and not to hold it necessary to conceive any respective inferiority of *hypostases*."

This term occasioned great dissensions in the ancient church; first amongst the Greeks, and afterwards amongst the Latins. In the council of Nice, *hypostasis* was defined to denote the same thing with *essence* or *substance*; so that it was heresy to say that Jesus Christ was of a different *hypostasis* from the Father; but custom altered the meaning of the term. In the necessity they were under of expressing themselves strongly against the Sabellians, the Greeks made choice of the word *hypostasis*, and the Latins of the word *persona*; a change which proved the occasion of endless disagreement. The phrase τρεις ὑποστασεις, used by the Greeks, scandalized the Latins, whose usual way of rendering ὑποστασις in their language was by *substantia*. The barrenness of the Latin tongue in theological phrases allowed them but one word for the two Greek ones, ουσια and ὑποστασις, and thus disabled them from distinguishing *essence* and *hypostasis*; for which reason they chose rather to use the term *tres personæ*, and *tres hypostases*. But an end was put to disputation, in a synod held at Alexandria about the year 362, at which St Athanasius assisted; and from this time the Latins made no great scruple of saying *tres hypostases*, nor the Greeks of saying *three persons*.

HYPOTHECA, in the *Civil Law*, an obligation by which the effects of a debtor are made over to his creditor, in security of his debt. The word comes from the Greek ὑποθηκη, *a thing subject to some obligation*, from the verb ὑποτιθημαι, *suppono*, I am subjected.

As the *hypotheca* is an engagement procured on purpose for the security of the creditor, various means have been employed to secure to him the benefit of the convention. The use of the pawn or pledge is the most ancient, which is almost the same thing with the *hypotheca*, all the difference consisting in this, that the pledge is put into the creditor's hands, whereas, in a simple *hypotheca*, the thing remained in the possession of the debtor. It was found more easy and commodious to engage an estate by a civil covenant than by an actual delivery. Accordingly the expedient was first practised amongst the Romans; and from them the Greeks borrowed both the name and the thing; only, the better to prevent frauds, they used to fix some visible mark on the thing, that the public might know it was hypothecated or mortgaged by the proprietor; but the Romans, looking on such advertisements as injurious to the debtor, forbade the use of them.

The Roman lawyers distinguished four kinds of hypothecs; the conventional, which was with the will and consent of both parties; the legal, which was appointed by law, and for that reason called *tacit;* the prætor's pledge, when by the flight or non-appearing of the debtor, the creditor was put in possession of his effects; and the judiciary, when the creditor was put in possession by virtue of a sentence of the court.

The conventional *hypotheca* is subdivided into general and special. The *hypotheca* is general, when all the debtor's effects, both present and future, are engaged to the creditor. It is special, when limited to one or more particular things. With regard to the tacit *hypotheca*, the civilians reckon no less than twenty-six different species of this genus.

HYPOTHENUSE, in *Geometry*, the longest side of a right-angled triangle, or that which subtends the right angle.

HYPOTHESIS, formed from ὑπο, *under*, and θεσις, *positio*, from τιθημι, *pono*, I put, is a proposition or principle which we suppose, or take for granted, in order to draw conclusions for the proof of a point in question.

Every conditional or hypothetical proposition may be distinguished into hypothesis and thesis. The first rehearses the conditions under which any thing is affirmed or denied; and the second is the thing itself affirmed or denied. Thus, in the proposition, a triangle is half of a parallelogram, if the bases and altitudes of the two be equal, the latter part is the hypothesis, and the former a thesis.

In strict logic, we are never to pass from the hypothesis to the thesis; that is, the principle supposed must be proved to be true, before we require the consequence to be allowed.

It has become common, since the time of Newton, to decry all reasoning from hypotheses, as useless and unphilosophical. But was not the theory of gravitation itself founded upon a conjecture, that is, upon an hypothesis? It was founded upon the supposition that the power which regulates the fall of heavy bodies also regulates the motion of the moon; a supposition upon which he proceeded to reason before it was verified by calculation. The subject of the use and abuse of hypotheses in philosophical inquiries has been admirably illustrated by Mr Stewart, in the second volume of his *Philosophy of the Mind;* and to that book we refer those who wish to form accurate notions on this subject.

HYPOTRACHELION, in *Architecture*, is used for a little frize in the Tuscan and Doric capital, between the astragal and annulets, and which is also called the *colerin* and *gorgerin*. The word is applied by some authors in a more general sense, to the neck of any column, or that part of its capital below the astragal.

HYPSISTARII (formed from ὑψιστος, *highest*), a sect of heretics in the fourth century, who were so called from the profession they made of worshipping the Most High God.

The doctrine of the Hypsistarians may be considered as an assemblage of Paganism, Judaism, and Christianity. They adored the Most High God with the Christians; but they also revered fire and lamps with the heathens, and observed the sabbath, and the distinction of clean and unclean things with the Jews.

The Hypsistarii bore a near resemblance to the Euchites, or Massalians.

HYRCANIA, in *Ancient Geography*, a country of the Farther Asia, lying to the south-east of the *Mare Hyrcanum* or *Caspium;* with Media on the west, Parthia on the south, and Margiana on the east.

HYSTERICAL AFFECTION, or *Passion* (formed from ὑστερα, *womb*), a disease in women, called also *suffocation of the womb*, and vulgarly *fits of the mother*. It is a spasmodico-convulsive affection of the nervous system, proceeding from the womb.

HYSTERON PROTERON, in *Grammar* and *Rhetoric*, a species of the hyperbaton, in which the proper order of construction is so inverted, that the part of any sentence which should naturally come first is placed last. Thus in Terence, *Valet et vivit*, for *vivit et valet;* and in Virgil, *Moriamur, et in media arma ruamus*, for *In media arma ruamus, et moriamur.*

HYTHE, a borough town of the county of Kent, in the parish of Saltwood, in the hundred of Horne, sixty-seven miles from London. It is one of the Cinque Ports, and as such returns one member to the House of Commons, who is chosen by about 420 voters. It consists chiefly of one long and well-built street, parallel to the shore, about a mile from the sea. In a vault under the church is a vast collection of dry human bones, which, according to tradition, are the remains of a great battle fought here between the Danes and the Britons antecedent to the Norman conquest. The inhabitants amounted in 1801 to 1365, in 1811 to 2318, in 1821 to 2181, and in 1831 to 2287.

I.

I, or *i*, the ninth letter and third vowel of the alphabet, is pronounced by throwing the breath suddenly against the palate, as it comes out of the larynx, with a small hollowing of the tongue, and nearly the same opening of the lips as in pronouncing *a* or *e*. Its sound varies; in some words it is long, as *high, mind;* in others short, as *bid, hid, sin;* in others, again, it is pronounced like *y*, as in *collier, onion;* and in a few it sounds like *ee*, as in *machine, magazine*, and the like. No English word ends in *i*, *e* being either added to it, or else the *i* turned into *y*. But besides the vowel, there is the *jod* consonant, which, because of its different pronunciation, has likewise a different form, thus, J, j. In English it has the soft sound of *g;* nor is it used excepting when *g* soft is required before vowels, where *g* is usually hard. Thus we say, *jack, jet, join*, instead of *gack, get, goin*, which would be contrary to the genius of the English language.

I, used as a numeral, signifies *one*, and stands for as many units as it is times repeated: thus I. one, II. two, III. three; and when put before a higher numeral, it subtracts itself, as IV. four, IX. nine, and so on. But when placed after it, as many are added to the higher numeral as there are I's added. Thus, VI. is 5 + 1, or six; VII. 5 + 2, or seven; VIII. 5 + 3, or eight. The ancient Romans likewise used IƆ for 500, CIƆ for 1000, IƆƆ for 5000, CCIƆƆ for 10,000. Further than this they did not go in their notation, but, when necessary, repeated the last number, as CCCIƆƆƆ, CCCIƆƆƆ, for 200,000; CCCIƆƆƆ, CCCIƆƆƆ, CCCIƆƆƆ, for 300,000; and so on. The ancients sometimes changed *i* into *u;* as *decumus* for *decimus; maxumus* for *maximus*, and so on. According to Plato, the vowel *i* is proper to express delicate but humble things, as in the verse of Virgil:

> Accipiunt inimicum imbrem, rimisque fatiscunt.

I, used as an abbreviature, is often substituted for the word Iesus, of which it is the first letter.

IAMBIC, in ancient poetry, a sort of verse, so called from its consisting either wholly, or in a great measure, of iambuses. See Iambus.

Ruddiman makes two kinds of iambic verse, viz. dimeter and trimeter; the former containing four feet, and the latter six. And as to the variety of feet, they consist wholly of iambuses, as in the two following verses of Horace:

```
      1    2    3    4    5    6
Dim.  Inar|sit æ|stuo|sius|
Trim. Suis|et i|psa Ro|ma vi|ribus|ruit.
```

Or a dactyle, spondee, anapest, and sometimes a tribrachys, obtain in the odd places; and the tribrachys also in the even places, excepting the last. Examples of all this may be seen in Horace. Thus,

```
1      2      3       4          5        6
Canidi|a tra|ctavit|dapes|
Vide|re prope|rantes|domum|
Quoquo|scele|sti rui|tis aut|cur dex|teris.
Prius|que cœ|lum si|det in|ferius|mari.
Aliti|bus at|que cani|bus homi|cid' He|ctorem.
Pavidum|que lepo|r' aut ad|venam laqueo|gruem.
```

IAMBUS, in the Greek and Latin prosody, a poetical foot, consisting of a short syllable followed by a long one; as in

> ᴗ – ᴗ – ᴗ – ᴗ –
> Θεου, λεγω, Deī, meas.

"*Syllaba longa brevi subjecta vocatur* iambus," as Horace expresses it; and he also calls the iambus a swift, rapid foot, *pes citus*.

The word, according to some, took its rise from Iambus, the son of Pan and Echo, who invented this foot; or, perhaps, who only used sharp, biting expressions to Ceres, when afflicted for the death of Proserpine. Others derive it from the Greek ἰος, *venenum*, poison; or from ἰαμβιζω, *maledico*, I rail or revile, because the verses composed of iambuses were at first used only in satire.

IBERIA, Spain, so called by the ancients, from the river Iberus or Ebro.

Iberia was also the name of an inland country of Asia, having to the west Colchis, with part of Pontus; to the north Mount Caucasus; on the east Albania; and on the south Armenia Magna. It is now the western part of Georgia.

IBYCUS, a Greek lyric poet who flourished 550 B. C., and of whose works there are only a few fragments remaining. It is said that he was assassinated by robbers, and that when dying he called upon some cranes he saw flying past to bear witness. Not long afterwards one of the murderers seeing some cranes, said to his companions, "There are the witnesses of Ibycus's death;" which being reported to the magistrates, the assassins were put to the torture, and having confessed the fact, were hanged. And hence arose the proverb *Ibyci Grues*.

ICE, a solid, transparent, and brittle body, formed of some fluid, particularly water, by means of cold.

M. Lemery observes, that ice is only a re-establishment of the parts of water in their natural state; that the mere absence of fire is sufficient to account for this re-establishment; and that the fluidity of water is a real fusion, like that of metals exposed to the fire; differing only in this, that a greater quantity of fire is necessary to the one than the other. Galileo was the first who observed that ice was lighter than the water which composed it; and hence it happens that ice floats upon water, its specific gravity being to that of water as eight to nine. This rarefaction of ice seems to be owing to the air-bubbles produced in water by freezing, and which, being considerably large in proportion to the water frozen, render the body so much specifically lighter. These air-bubbles, during their production, acquire a great expansive power, so as to burst the containing vessels, though ever so strong.

M. Mairan, in a dissertation on ice, attributes the increase of its bulk chiefly to a different arrangement of the parts of the water from which it is formed; the icy skin on the water being composed of filaments, which, according to him, are found to be constantly and regularly joined at an angle of 60°; and which, by this angular disposition, occupy a greater volume than if they were parallel. He found the augmentation of the volume of water by freezing, in different trials, a fourteenth, an eighteenth, a nineteenth, and, when the water was previously purged of air, only a twenty-second part; that ice, even after its formation, continues to expand by cold; for, after water had been frozen to some thickness, the fluid part being let out by a hole in the bottom of the vessel, a continuance of the cold made the ice convex; and a piece of ice which was at first only a fourteenth part specifically lighter than water, on being exposed some days to the frost, became a twelfth part lighter. To this cause he attributes the bursting of ice on ponds.

Though it has been generally supposed that the natural crystals of ice are stars of six rays, forming angles of 60° with each other, yet this crystallization of water, as it may properly be called, seems to be as much affected by circumstances as that of salts. Hence we find a considerable difference in the accounts of those who have undertaken to describe these crystals. M. Mairan informs us that they are stars with six radii; and his opinion is confirmed by observing the figure of frost on glass. M. Romé de l'Isle determines the form of the solid crystal to be an equilateral octahedron; M. Hassenfratz found it to be a prismatic hexahedron; but M. d'Antic found a method of reconciling these seemingly opposite opinions. In a violent hail-storm, where the hailstones were very large, he found that they had sharp wedge-like angles of more than half an inch; and in these he supposed it impossible to see two pyramidal tetrahedra joined laterally, and not to conclude that each grain was composed of octahedrons converging to a centre. Some had a cavity in the middle; and he saw the opposite extremities of two opposite pyramids, which constitute the octahedron; he likewise saw the octahedron entire united in the middle; all of them were therefore similar to the crystals formed upon a thread immersed in a saline solution. On these principles M. d'Antic constructed an artificial octahedron resembling one of the largest hailstones, and found that the angle at the summit of the pyramid was 45°, but that of the junction of the two pyramids 145°. It is not, however, easy to procure regular crystals in hailstones, where the operation is conducted with such rapidity; in snow and hoar-frost, where the crystallization goes on more slowly, our author is of opinion that the rudiments of octahedra may be discovered. (See the section on CONGELATION, in the article COLD.)

Blink of the Ice.

Blink of the ICE, is a name given by the pilots to a bright appearance near the horizon, occasioned by the ice, and observed before the ice itself is seen.

ICE-Boats, boats so constructed as to sail upon ice, and which are very common in Holland. They go with incredible swiftness, sometimes so quickly as to affect the breath, and are found very useful in conveying goods and passengers over lakes and great rivers. Boats of different sizes are placed in a transverse form upon a two-and-a-half or three-inch deal board. At the extremity of each end are fixed irons, which turn up in the form of skaits. Upon this plank the boat rests, and the two ends serve as out-riggers to prevent oversetting; whence ropes are fastened that lead to the head of the mast in the nature of shrouds, and others passed through a block across the bowsprit. The rudder is made somewhat like a hatchet with the head placed downwards, which being pressed down, cuts the ice, and serves all the purposes of a rudder in the water, by enabling the helmsman to steer.

Ice-House.

ICE-House, a repository for ice during the summer months. The aspect of ice-houses should be towards the east or south-east, for the advantage of the morning sun to expel the damp air, as that is more pernicious than warmth; for which reason trees in the vicinity of an ice-house tend to its disadvantage. The best soil for an ice-house to be made in is chalk, as it conveys away the waste water without any artificial drain; the next to that is loose stony earth or gravelly soil.

Ice may be preserved in a dry place under ground, by covering it well with chaff, straw, or reeds. Great use is made of chaff in some places of Italy to preserve ice; the ice-house for this purpose need only be a deep hole dug in the ground on the side of a hill, from the bottom of which they can easily carry out a drain, to let out the water which is separated at any time from the ice, that it may not melt and spoil the rest. If the ground is tolerably dry, they do not line the sides with any thing, but leave them naked, and only make a covering of thatch over the top of the hole. This pit they fill either with pure snow, or else with ice taken from the purest and clearest water; because they do not use it, as we do in England, to set the bottles in, but really mix it with the wine. They first cover the bottom of the hole with chaff, and then lay in the ice, not letting it anywhere touch the sides, but ramming in a large bed of chaff all the way between; they thus carry on the filling to the top, and then cover the surface with chaff. Ice packed in this manner will keep as long as they please. When they take any of it out for use, they wrap up the lump in chaff, and it may then be carried to any distant place without waste or melting.

It appears from the investigations of Professor Beckman, in his History of Inventions, that the ancients, from the earliest ages, were acquainted with the method of preserving snow for the purpose of cooling liquors in summer. "This practice," he observes, "is mentioned by Solomon; and proofs of it are so numerous in the works of the Greeks and the Romans, that it is unnecessary for me to quote them, especially as they have been collected by others. How the repositories for keeping it were constructed we are not expressly told; but it is probable that the snow was preserved in pits or trenches.

"When Alexander the Great besieged the city of Petra, he caused thirty trenches to be dug, and filled with snow, which was covered with oak branches, and which kept in that manner for a long time. Plutarch says that a covering of chaff and coarse cloth is sufficient; and at present a like method is pursued in Portugal. Where the snow has been collected in a deep gulf, some grass or green sods, covered with dung from the sheep pens, is thrown over it; and under these it is so well preserved, that, the whole summer through, it is sent the distance of sixty Spanish (nearly 180 English) miles to Lisbon.

"When the ancients, therefore, wished to have cooling liquors, they either drank the melted snow, or put some of it in their wine; or they placed jars filled with wine in the snow, and suffered it to cool there as long as they thought proper. That ice was also preserved for the like purpose, is probable from the testimony of various authors; but it appears not to have been used so much in warm countries as in the northern. Even at present snow is employed in Italy, Spain, and Portugal; but in Persia ice. I have never any where found an account of Grecian or Roman ice-houses. By the writers on agriculture they are not mentioned."

Ice-Island.

ICE-Island, a name given by sailors to a great quantity of ice collected into one huge solid mass, and floating about upon the seas near or within the polar circles. The motion of the lesser pieces is as rapid as the currents: the greater, which are sometimes two hundred leagues long, and sixty or eighty broad, move slowly and majestically; often fix for a time, immoveable by the power of the ocean, and then produce near the horizon that bright white appearance called the *ice-blink*. The approximation of two great fields produces a most singular phenomenon; it forces the lesser (if the term can be applied to pieces of several acres square) out of the water, and adds it to the surface; a second, and often a third succeeds, so that the whole forms an aggregate of a tremendous height. These float in the sea like so many rugged mountains, and are sometimes five or six hundred yards thick; but the far greater part is concealed beneath the water. These are continually increased in height by the freezing of the spray of the sea, or the melting of the snow which falls on them. Those which remain in this frozen climate receive continual additions; others are gradually wafted by the northern winds into southern latitudes, and melt by degrees by the heat of the sun, till they waste away, or disappear in the boundless element.

ICEBERGS are large bodies of ice filling the valleys between the high mountains in northern latitudes. Among the most remarkable are those of the east coast of Spitzbergen. The glaciers of Switzerland seem contemptible when compared to these, but present often a similar front into some lower valley. At times immense fragments break off and tumble into the water with an alarming splash. Frost sports wonderfully with these icebergs, and gives them majestic and singular forms. Masses have been seen assuming what an Arabian tale would scarcely dare to relate. Icebergs are the creation of ages, and receive annually additional height by the falling of snows, and of rain, which often instantly freezes, and more than repairs the loss occasioned by the influence of the sun.

ICELAND, one of the largest islands in Europe (being little inferior, in point of superficial extent, to Ireland), is situated in the north part of the Atlantic Ocean, between the 63d and 67th degrees of north latitude, and the 12th and 25th degrees of west longitude. Its extreme length from east to west is about 280 miles, and its breadth from north to south varies from 180 to 200.

History.

The precise period at which this island was discovered and first colonized is unknown; but, from the Landnamabok, an ancient Icelandic chronicle, and a work generally relied upon as authentic, we learn that the Norwegians were the first settlers upon its coasts. Naddodr, a famous pirate of that adventurous nation, was, on his return to the Feroe Islands from a predatory excursion, about the year 860, driven by a tempest upon the coast of Iceland. He ascended to the summit of a mountain, but observing around him neither the vestige of a human residence, nor aught else than vast and trackless fields of snow, he immediately abandoned it. Probably aware of this discovery, Gardar Svarfarson, a Swede, followed the same track a few years afterwards, and, succeeding in circumnavigating the country, discovered it to be an island. He there spent the winter, but finding little inducement to make it a permanent residence, he in the following spring returned to Norway. The third adventurer on this coast was one Floki, another celebrated Norwegian pirate, who, during two seasons, explored a considerable portion of the southern and western coasts. His attempt at forming a permanent settlement proved, however, like that of his predecessor, a failure; his cattle died, his expected crops were ruined, and, after experiencing numerous distresses and hardships from the inclemency of the weather, he determined to repair to a warmer region, and gave to the island at his departure the name by which it has ever since been known. That this name, and the report which he spread on his return, of the inhospitable nature of the island, were principally the effect of prejudice and disappointment, is evident from the contradictory account given of it by his companions, one of whom thought he could only convey an adequate idea of its richness and fertility by declaring that butter dropped from every plant.

These expeditions, though affording a slight knowledge of the country, would probably not have led to its colonization, had not disturbances in Norway induced some of the inhabitants of that country to quit their native soil. Harold Harfagra having subdued most of the petty princes of that country, put an end to the system of liberty and independence which the inhabitants of Norway had hitherto enjoyed; and thus drove many even of its nobility, with their families and dependents, from their homes. A body of these voluntary exiles, under the conduct of Ingolf, one of the discontented subjects, sailed from Norway, A. D. 874, from which year the Icelanders date the occupation of their island. When Ingolf approached the coast of Iceland, we are informed that he threw into the sea the wooden door of his former habitation in Norway; and finding it some time afterwards cast upon the shore at Reikiavik, he fixed his abode on the spot where the capital of the island now stands. He was followed by several others, and in a short time considerable portions of the southern and eastern districts of the island were taken possession of. Harold, it appears, did not at first oppose the emigration of his subjects; but afterwards finding it carried on to a great extent, he imposed a fine of four ounces of fine silver upon every person who should leave Norway to settle in Iceland. The Landnamabok, already mentioned, whose object was to afford a picture of the colonization of the island, describes with singular minuteness the arrival and spreading of the different settlers, and records, together with those of the Norwegians, the names of many Danes and Swedes, and even some Scotch and Irish, who at this period selected Iceland as their place of residence. The natural consequence of progressive colonization under the feudal tenure which was thus produced, was frequent contention between the new comers and those who had already settled in the country. To obviate these, a chief was named, under whose guidance and direction the concerns, interests, and feelings of the yet separate communities might be regulated and assimilated. This beneficial change was effected A. D. 928, and a republican form of government was thus established, well calculated to provide for the emergencies which gave it birth. We say a republican form of government; because, though there was only one supreme magistrate, who decided all disputes, and presided at the *all-thing*, or great general assembly of the nation, still he was elected to this office by the free choice of the people, and retained it no longer than while he preserved their confidence. This state of liberty the Icelanders enjoyed with uninterrupted harmony for the space of nearly 400 years. During this period, education, literature, and even the refinements of poetical fancy, flourished amongst them; and the well-known *sagas* or tales of the country, the most remarkable literary productions of that dark age, were principally penned prior to the fourteenth century.

The ancient Icelanders possessed, as is still the case with their posterity, few of the luxuries or refinements of life; and were occasionally exposed to severe privations, from the nature of their soil, and the seasons under which they lived. There is reason, however, to believe, though the fact cannot with perfect accuracy be ascertained, that the climate of Iceland was once less austere than it now is, and that not only trees and shrubs, but even corn, were grown upon the island. Of the ancient existence of the former, the trunks occasionally discovered in the bogs afford pretty satisfactory evidence. Corn of any description is not now a native of the island; and a few birch twigs afford the only approach towards timber. Like the present inhabitants, the ancient Icelanders were much dispersed over the country, their habitations being seldom grouped together, but placed wherever the situation and nature of the soil appeared suitable. Their occupations and modes of life appear also to have borne much similitude. The produce of the farm, and the capture of fish, afforded them, as they do their posterity, the principal means of subsistence; and their traffic with foreign countries made a valuable addition to their domestic comforts. The moral habits of the people were good, though, prior to the introduction of Christianity, in the year 1000, they were blended with superstition and some unnatural customs, such as the exposure of their infants. The putting down of heathenism is not the least remarkable event in the early history of Iceland. Frederic, a bishop of Saxony, was the first who preached Christian doctrines in this distant land. The propagation of his tenets, however, met

Iceland. with every species of opposition; but the numbers who adopted them gradually increased so considerably, that the national assembly which met at Thingvalla in the year 1000 took the matter into consideration. Whilst the question was warmly debated, the story told is, that a messenger hurried into the assembly and announced that fire had burst from the earth in the southern part of the country, and was carrying destruction before it. The heathen party instantly exclaimed that this was the vengeance of the gods against the presumption of their opponents. But Snorro, who was a zealous advocate for the Christian cause, immediately demanded, "For what reason was the anger of your gods kindled when the very rock was burning on which we stand?" Thingvalla being in the midst of a volcanic country, and precipitous cliffs of lava surrounding the place of public assembly. The promptitude of the reply had the desired effect, and ultimately procured a decision in favour of the Christians. On the promulgation of Christianity, all religious contest was suspended; the whole people espoused the new faith; and a church establishment was soon afterwards formed. The Icelanders appear to have equalled the blindest of their fellow Catholics in their attachment to the hierarchy; and it was not till the year 1551 that the Reformation, under Christian III. of Denmark, found its way into the island. Since that period the form and ceremonies of the Icelandic church have been strictly Lutheran, though, from the poverty of the country, their churches are in general extremely wretched, and the pittances allotted to their clergy still more so.

But to return to earlier periods. We are indebted to the enterprise of the ancient inhabitants of Iceland for the discovery both of Greenland and Newfoundland. A mariner named Eric accidentally approached the former of these countries about the year 972, and was so delighted with his discovery, that he gave it the name which it still bears. His flattering accounts of the country had the desired effect of alluring his countrymen to its shores; and in this he so far succeeded, as in a short time to form an extensive and thriving settlement. The colonists maintained a constant commercial intercourse with Iceland and Norway; and the records of the settlement come down uninterruptedly to the beginning of the fifteenth century, when at once every trace and vestige of it was lost. The causes of this singular fact have never yet been fully ascertained, although the most probable supposition is, that an accumulation of ice took place about this time on the Greenland coast, which prevented the access to it by sea. The breadth of the sea between the two countries does not exceed 100 miles; and yet the fate of this ancient colony, commonly called by distinction Old Greenland, is quite unknown. The northern shores of America were first known from Biono Heriolforn, a native of Iceland, being driven upon them during a voyage to Greenland in 1001. Attracted by the account of this discovery, Leif, another enterprising navigator, pursued the same route considerably farther southwards, and finding an agreeable and pleasant country, he wintered there, giving it, from the circumstance of wild vines growing on it, the appellation of Vinland. This was subsequently, to a partial extent, colonised by the Icelanders; but few particulars are known of their progress, and what ultimately became of the colony is now a mere matter of speculation.

The independent and happy state of Iceland was not destined to be uninterrupted. About the year 1250, party disputes and internal feuds arose, which the ambition of the mother country enabled Haco, the then king of Norway, to foment. In 1261 a formal proposal was consequently made in the national council, to submit to that sceptre; but in doing so, the Icelanders stipulated that they should be allowed to retain their ancient laws and privileges, that they should be exempt from taxes, and that the annual importation of the most necessary articles of foreign produce should be secured to them. For upwards of a century Iceland was under the dominion of Norway, without any occurrence taking place of the slightest importance; and when in the year 1380 that country became subject to Denmark, the island was transferred to the same power, without tumult or opposition. The change in the constitution of the island, from its annexation to a European monarchy, naturally produced a corresponding change in the character and habits of the people. Not that the foreign yoke was a tyrannical one, otherwise a portion at least of the ancient vigour and activity of the inhabitants would have displayed itself in occasional acts of insurrection. On the contrary, the Danish monarchs not only exercised their sway with a lenient and forbearing hand, but paid much attention to the welfare and the wants of this remote part of their dominions; and thus repose and security succeeding to internal broils, produced a state of comparative apathy and indolence. Rank and property became more nearly equalized, and the trade of the country was gradually transferred to the natives of other kingdoms. A plague which devastated the island in 1402, and carried off, it is said, nearly two thirds of the whole population, tended still further to depress the spirit of the people, and destroy the strength and prosperity of the country. The reformation of religion, which, as above stated, took place in Iceland in the year 1551, was the first dawn of an improvement amongst the natives, which the introduction of printing and the establishment of a press about the same period aided greatly in extending. The recent history of Iceland is principally characterised as a record of physical calamities, which, from 1707, when the ravages of the small-pox carried off sixteen thousand of its inhabitants, down to 1753 and 1759, when the inclemency of the seasons created the most dreadful and distressing famines, and lastly, the memorable year 1783, when the great eruption from the Skaptaa Yokull took place, have rarely ceased in one form or another to devastate the island. The scene of this last-mentioned eruption is amongst lofty mountains in the interior of the island, known only to the natives by the remote view of their snow-clad summits. From this desolate and unfrequented region, Sir George Mackenzie remarks, vast torrents of lava issued forth, overwhelming all before them, and filling up the beds of great rivers in their progress towards the sea. For more than a year, a dense cloud of smoke and volcanic ashes covered the whole of Iceland, extending its effects even to the northern parts of continental Europe; the cattle, sheep, and horses of the country were destroyed; a famine, with its attendant distresses, broke out amongst the inhabitants; and the small-pox invaded the island at the same time, with its former virulent and fatal effects. From these combined causes, more than eleven thousand people perished during the period of a few years; an extent of calamity which can only be understood, by considering that this number forms nearly a fourth part of the whole population of the country. The destruction of the fishery upon the southern coasts of the island by these volcanic eruptions was another more permanent source of distress, and one which is not even now fully removed.

Government, laws, &c.

The government of Iceland is committed to an officer appointed by the crown of Denmark, who is occasionally a native of the island, but more frequently a Dane by birth. This supreme magistrate has the title of Stiftamtman, and is intrusted with a general superintendence of every department. Under him are the amtmen or provincial governors, each of whom rules one of the four provinces of the island, and possesses a similar jurisdiction over his respective quarter, as his superior officer does over the whole island. Each province again is divided into syssels or shires, over which the sysselmen preside. This office is likewise in the appointment of the crown; and, on account of its importance, it is always given to one of the most respectable landed proprietors within the district. The rank of sysselman corresponds in some degree to that of sheriff in this country. The hreppstiore is a subordinate parochial officer, whose duty it is to attend to the condition of the poor, and to assist the sysselman in the preservation of the peace. He is usually chosen from among the farmers; whilst the forlikunarmen are those appointed as arbiters for the decision of disputes among the parishioners. The laws of Iceland, like the general form of government as established nearly six hundred years ago, have undergone little important alteration; but the judicial changes have been more considerable, and the forms of justice in most respects now resemble those of Denmark.

Crimes are rare; the gentle and peaceable disposition of the natives, their moral and religious education and sober habits, act as preventives of such as are of a flagrant description. Small thefts, especially of sheep, are the most frequent; but the high court has seldom to decide more than six or eight cases annually. The whip is the only punishment applied in the country, excepting fines; those who are punished with hard labour or banishment being sent to Copenhagen.

There are about 194 parishes or livings on the island; but the clergy number at least 300, as many of the parishes have two churches, the great distance and the danger of travelling, particularly in winter, when the rugged fields of lava are covered with snow, making it frequently impossible for all the peasantry of the same parish to attend at one church. The clergy are partly supported by a species of tithes, which are mostly paid in kind. These stipends, however, are extremely miserable; the largest in the island not exceeding 185 dollars, and the average being little above 35 dollars, or L.6 sterling, per annum. They must therefore depend almost entirely for subsistence on their glebe land and their stock of cattle, and a small pittance they are entitled to for the few baptisms, marriages, and funerals that occur among their parishioners. "The clergy," observes Mr Barrow, "almost universally submit to every species of drudgery from necessity. Their incomes are too small to allow them to hire and feed labourers; and nothing is more common than to find the parish priest in a coarse woollen jacket and trousers, or skin boots, digging peat, mowing grass, and assisting in all the operations of haymaking. They are all blacksmiths also from necessity, and the best shoers of horses on the island. The feet of an Iceland horse would be cut to pieces over the sharp rock and lava if not well shod. The great resort of the peasantry is the church; and should any of the numerous horses have lost a shoe, or be likely to do so, the priest puts on his apron, lights his little charcoal fire in his smithy (one of which is always attached to every parsonage), and sets the animal on his legs again." Their poverty was quaintly but very contentedly alluded to by one of themselves, when he said, in a few lines he composed on occasion of Mr Henderson's visit to his mansion:—"Ever since I came into the world I have been wedded to poverty, who has now hugged me to her bosom these seventy winters all but two; and whether we shall ever be separated here below, is only known to Him who joined us together."

The clergyman of the parish having thus to undergo the same toils and hardships as the most humble of his flock, and enjoying no superior comforts or refinements, must feel that it is by his intellectual attainments only he can retain that station, and command that respect from his parishioners, which it is so necessary for him to possess. Literary pursuits are therefore the principal occupation of the clergy during the long and dreary period of winter; and it is astonishing, considering the difficulties in their way, the progress most of them have made. The history and literature of the more refined nations of Europe now form a part of their studies. The English language, in which they find so many words of their own, and so many borrowed from the Latin, is cultivated by many of the clergy. The German they find still more easy; the Danish and Norwegian languages approximate to their own; and many of the choicest works in all these dialects have been translated into Icelandic. The present state of literature in Iceland thus appears to be of a different description from what it was in ancient times. Its supposed decline is the subject of general complaint, though in point of fact it has only changed its character from the heroic and romantic to the useful and intelligible. Von Troil, in comparing the state of the sciences in the island to the four stages of human life, remarks that "their infancy extended to the year 1056, when the introduction of the Christian religion produced the first dawn of light. They were in their youth till 1110, when schools were first established, and the education and instruction of youth began to be more attended to. Their manly age lasted till about the middle of the fourteenth century, when Iceland produced the greatest number of learned men. Old age appeared towards the end of this same fourteenth century, when the sciences gradually decreased, and were almost entirely extinct, no work of any merit appearing. History now drooped her head, poetry had no relish, and all other sciences were enveloped in darkness." But a new dawn of knowledge spread rapidly over the island after the Reformation; and the introduction of the printing press produced the same beneficial effects in Iceland as in other parts of Europe. A very important change took place in the nature of the studies pursued; and the clergy in particular, instead of occupying their time in making and transcribing *eddas* and *sagas*, that is, political and historical romances, have turned their attention to sober history, to the collection and registration of events, and to other literary productions of more intrinsic value, which the printing press, still actively employed on the small island of Vidoe, opposite Reikiavik, affords them the opportunity of turning to account.

There are no public hospitals, or charitable institutions of that description, on the island; the sick and the poor being almost wholly supported by their own families. Indeed a sort of disgrace attaches to those who send them away to be taken care of by strangers, even though maintained at their own expense. On the other hand, there is an important collegiate school at Bessestad, which may well be considered as the only public institution of importance in the country. It is intended principally for the education of young men destined for the church, and is attended by about forty scholars. There are three masters, the one, professor of theology, instructs the pupils in Hebrew and Greek, as far as the Greek Testament, and Xenophon; the second, who is the lecturer, teaches them Latin, history, mathematics, and arithmetic; and the third the Danish, Norwegian, German, and Icelandic languages. Their attendance is constant from October to May, the intermediate months being the period of vacation, when the students go to their several homes. The funds appropriated for this excellent institution are said to be sufficient to pay the teachers, and to afford board, books, and clothing to the scholars gratis.

Property is held either of the crown or in fee simple; the crown lands and many others are let to farmers, on what may almost be called perpetual leases. The rent is paid in two parts; the land rent, fixed at an old valua-

Iceland. tion, which it has not been found necessary to alter, and a rent for the number of cattle which it is calculated the farm is able to support; and these are transferred from one tenant to another, each succeeding one taking them, and leaving a similar number on quitting the farm. This, however, does not prevent a farmer keeping as much stock as he can maintain, without paying an additional rent. The tenant is for life, provided he does not injure the farm; but he may quit whenever he pleases, on giving six months' notice. His rent is generally paid in produce, on the coast in fish, in the interior in wool, tallow, butter, sheep, &c. or, according to agreement, in money. Individuals who cultivate their own properties, and tenants who are in easy circumstances, generally employ one or more labourers, who, besides board and lodging, have from ten to twelve dollars of annual wages. In Iceland, as in Norway, there is no such thing as entailed property, and the law of descent excludes primogeniture. If an individual dies intestate, his estate is sold or valued, and divided amongst the children, so as to give equal shares to the sons, and half shares to the daughters. If, however, any of the brothers can pay the shares to his brothers and sisters, it is generally arranged that the freehold estate be made over to him, in order to retain it in the family.

Population. The gross population of Iceland is about 53,000, a very scanty proportion for an island whose surface is to that of Ireland as four to five; but that surface, it is true, from its nature, and the character of the climate, is perhaps as unfavourable as any which exists between the limits of the two arctic circles. Deducting the areas of the numerous fiords with which it is intersected, the square contents of the land may be calculated at 37,388 statute miles; but as the centre of the island consists entirely of snowy and uninhabited mountains, the peopled portion cannot be considered more than 25,000 square miles; and the population therefore will not much exceed two persons on each square mile. The number of births in the year 1832 was 2516; and the number of deaths during the same year amounted to 1390, of which 784, considerably more than one half, were children under ten years of age. The whole population is employed either in farming, which occupies about three fourths of them, or in fishing. Other employments do not exist, nor is there any other class of people or townsmen, save the small number of merchants in Reikiavik and the other trading establishments. Every branch of industry is therefore domestic, and confined chiefly to articles of clothing, such as coarse cloth, gloves, mittens, and stockings. The peasantry are generally ingenious, and manufacture such simple pieces of furniture as their cottages require; some also aspire to make trinkets of silver, and articles from the walrus tusks. The trade of Iceland has never been managed in a way to be of important benefit to its inhabitants, those who are engaged in it being almost exclusively Danes, and other foreigners. Of late years, however, there has been an annual export of from 1,000,000 to 1,200,000 pounds of raw wool, besides about 200,000 pairs of knitted stockings, and 300,000 mittens, or gloves without fingers. The Iceland sheep have remarkably fine fleeces of wool, which the farmers in the spring of the year take off whole; their weight being usually from four to five pounds. The other exports of Iceland are dried fish, salted cod, and other species, for the quality of which the fishing banks of the island are celebrated, but which latterly have been much invaded by the French and Dutch fishermen, to the great grievance of the nation. Fish-oil, whale-blubber, skins, eider-down, feathers, and the *lichen Islandicus* for medicinal purposes, may also be included amongst their list of exports. These the natives dispose of to the Danish merchants in exchange for coffee, sugar, tobacco, snuff, a small quantity of brandy, rye and rye-bread, biscuit, wheaten flour, salt, soap, and such other small articles as are in constant use for domestic purposes. Those who can afford it purchase a supply of linens and cottons, which of late years have become of more common use, and which must tend greatly to cleanliness, and the prevention of those diseases which woollen clothing worn next the skin tends to engender. The traffic thus occasioned takes place in the early part of summer, and whilst it lasts creates a kind of fair, with no little bustle and business, in the capital. All the articles brought from the interior for sale at the sea-ports, and all those taken back for winter consumption, are transported on pack-horses. There is not, in fact, in all Iceland such a machine as a wheel-carriage; and indeed if there were, they would be useless, as there is nothing in the shape of a road on which they could move.

The Icelanders are generally middle sized and well made, though not very strong. Their manners are exceedingly simple, and they are very respectful as well as obliging to strangers. Though their poverty disables them from imitating the hospitality of their ancestors in all respects, yet they cheerfully give away the little they have to spare, and express the utmost satisfaction if the gift shall have proved acceptable. They possess but few peculiar customs, and those not of particular interest. Their sole occupation during summer is to provide means of subsistence for the winter season; and when confined during the dreariness of an arctic winter to their huts, their great source of amusement is the tales of olden times, when the learning of their country rendered it renowned in every quarter of Europe. "Being of quiet and harmless dispositions," says Sir George Mackenzie, "having nothing to rouse them into a state of activity, nothing to inspire emulation, no object of ambition, the Icelanders may be said merely to live. But they possess innate good qualities, which, independently of the consciousness of their former importance, have preserved their general character as an amiable community. They have indeed become negligent with respect to the cleanliness of their persons and dwellings, but they deserve a high place in the scale of morality and religion. To religious duties they are strictly attentive; and though the clergy are not generally raised above the level of the peasantry in any respect but in their sacred office, yet they have been able to preserve the regard due to those who are considered as peculiarly the servants of the Supreme Being." The poor Icelander, too, is strongly attached to his native soil, and, like the Swiss, has been known to throw up lucrative appointments which he held elsewhere, for the sake of rejoining his family and friends on the island, being never so happy as when he sees a prospect of returning to it.

Topography. Few countries in the world present a more forbidding aspect, or have less apparently to invite the approach either of the traveller or the merchant, than Iceland. The appellation given it by its first discoverers seems still peculiarly its own; and if the statement be accurate, of its having in former days grown considerable forests, whilst now scarce a shrub will rear its head, there is little probability of that name ever being belied. "Imagine to yourself," says Von Troil, "a country which, from one end to the other, presents to your view only barren mountains, whose summits are covered with eternal snow, and between them fields divided by vitrified cliffs, whose high and sharp points seem to vie with each other to deprive you of the sight of a little grass, which scantily springs up among them. These same dreary rocks likewise conceal the few scattered habitations of the natives, and nowhere a single tree appears which might afford shelter to friendship and innocence. The prospect before us, though not pleasing, was uncommon and surprising. Whatever presented itself to our view bore the marks of devastation; and our eyes, accus-

Iceland.

tomed to behold the pleasing coasts of England, now saw nothing but the vestiges of the operation of a fire, Heaven knows how ancient." Nor does Reikiavik, the capital of the country, the residence of the governor, the centre of its trade, present a much more inviting prospect to a stranger on his arrival. "He perceives," says Mr Barrow, "only a long row of houses, or rather the upper parts of houses, running parallel to and close behind a rising beach of a black shingle, their red or brown roofs being the most conspicuous, and the tops of the doors only, and perhaps about half of a row of windows, peeping above the said beach; but he sees enough of them to satisfy himself that they are of a low, mean character. On each extremity of this line of houses he will observe a rising eminence, scarcely deserving the name of a hill, on which he will perceive a number of sod or turf huts, raised a little, and but a little, above the level of the ground; their roofs, and generally their sides too, verdant enough and well clothed with grass, the abodes chiefly of fishermen, labourers in the merchants' employ, and idlers, of which there are not a few sauntering about. Among these hovels, or rather above them, on the western eminence, stands conspicuously the house of the physician-general of Iceland, or perhaps more properly surgeon and apothecary of Reikiavik; for he acts in all these capacities; which tall building, speaking comparatively with its neighbours, is kept in countenance by a still taller one, the only windmill on the island." "The lower part of their turf huts is built of rude stones to the height of about four feet, and between each row layers of turf are placed with great regularity, to serve instead of mortar, and in fact to keep out the wind. A roof of such wood as can be procured rests upon these walls, and is covered with turf or sods. A window is a luxury; a cask or barrel, with the two ends knocked out, answers the purpose of a chimney; but the smoke is frequently allowed to escape through a hole in the roof. The only fire ever burnt within their walls is that of the kitchen, which forms a small separate apartment, frequently detached."

The surface of the country is for the most part highly mountainous and rugged; some of the yokuls or snow-capped eminences, as the Snaefell, the Skaptaa, Kateja Torsa, and Hecla, rising to the height of from 4000 to 6000 feet above the sea. The centre of the island, however, is traversed by considerable plains, some of which are covered with tolerable pasture, whilst others form extensive wastes, morasses, and fields of lava. It is also watered by a number of large rivers, which, from the rapid melting of the snows in summer, present a turbid, and some of them so white an appearance, that they are denominated from that circumstance. The smaller streams which rise in the lower grounds are however transparent, and are celebrated for the abundance and beauty of the salmon which frequent them. There are also a number of lakes, of which the principal are called Thingvalla Vatn, an expanse of water from ten to fifteen miles in length, and six to eight in width, on whose banks the great assemblies of the nation used to be held; My Vatn, in the north-eastern extremity of the island; and Fiske Vatn, a lake so designated from the fine fish it affords to the inhabitants of the midland districts.

The coast, like that of Norway, is in every direction deeply indented with creeks and arms of the sea; few of them, however, afford safe anchorage; and along the southern coast, eastward from where the great river Elvas empties itself into the sea, there are extensive shoals, formed partly, no doubt, by the depositions of the rivers proceeding from the great range of yokuls to the eastward of Mount Hecla, but principally from the remains of volcanoes, which, like the Sabrina and Graham Islands, have at one period appeared above the surface, but from the action of the waves have subsequently sunk below it. It is extremely probable that Iceland owes its origin to some great convulsion of nature; for no part of the globe presents such a number of volcanic mountains, so many boiling springs, or such immense tracks of lava. The frequent and long-continued eruptions of its volcanoes are all on record in the historical annals of the island; their number since the year 1004 is stated at sixty-five. Of Hecla no less than sixteen great eruptions are mentioned; but, with the exception of that in 1818, this celebrated mountain has been in a quiescent state since the middle of last century. By far the most dreadful occurrence of this description was that already mentioned, which took place from the great range of the Skaptaafell Yokul in the year 1783; an eruption which devastated the finest portion of the island, and produced famine and disease amongst its inhabitants to an extent scarcely credible.

Geysers.

The boiling springs of Iceland have long attracted the attention of scientific men, and they are assuredly amongst the most curious and most remarkable phenomena which it presents. These are very numerous in many quarters of the island; but it is to the fountains termed the Geysers that we would now particularly allude. These extraordinary springs are situated in the western part of the island, in a small plain sixteen miles north of the village of Skalholt. The siliceous depositions of the waters of the Great Geyser have formed for it a basin about fifty-six feet in the greatest diameter, and fifty-two in the narrowest, a projection from one side causing the circumference to deviate from a perfect circle. A mound has thus been produced, which rises considerably above the surface of the plain, and slopes on all sides to the distance of a hundred feet or thereabouts, from the borders of the basin on its summit. The basin is from four to five feet deep, and slopes a little, like a saucer, towards the centre. At this point there is a cylindrical pipe or tube, about twelve feet in diameter and seventy feet deep, up which the boiling water rises and the eruptions burst forth. At intervals of some hours, when the basin is full, explosions are heard from below like the distant firing of cannon, and at the same time a tremulous motion of the ground is felt around the basin. "We observed," remarks Sir John Stanley, "the water in the basin to be much agitated; it boiled violently, and heaved as if some expansive power were labouring beneath its weight, and some of it was thrown up a few feet above the basin. Again there were two or three shocks of the ground, and a repetition of the same noise. In an instant the surrounding atmosphere was filled with volumes of steam rolling over each other as they ascended, in a manner inexpressibly beautiful, and through which columns of water shivering into foam darted in rapid succession to heights which at the time we were little qualified to estimate, but afterwards ascertained by means of a quadrant to be about ninety-six feet. At last, the water having filled the basin, it rolled in great waves over its edge, and forming numerous rills, made its way down the sides of the mound. Much was lost in vapour also, and still more fell to the ground in heavy showers of spray. The intervals at which the several jets succeeded each other were too short for the eye to distinguish. As they rose out of the basin, they reflected by their density the purest and most brilliant blue. In certain shades the colour was green, like that of the sea; but in their farther ascent all distinction of colour was lost, and the jets, broken into a thousand parts, appeared white as snow. Several of them were forced upwards perpendicularly; but many, receiving a slight inclination as they burst from the basin, were projected in beautiful curves, and the spray which fell from them, caught by a succeeding jet, was hurried away still higher than it had been perhaps before. The jets were made with inconceivable velocity, and those which escaped uninterrupted terminated

Iceland. in sharp points, and lost themselves in the air." After continuing for some minutes, the explosions cease, when the pipe and basin are both found empty.

Such are the phenomena presented during an eruption of the Great Geyser. In external appearance, as well as in the magnitude and violence of its ejections, this Geyser differs materially from the other two principal springs in its vicinity. Indeed, although it has been satisfactorily ascertained from historical records that they have been playing for the last six hundred years, yet very material changes are evidently taking place from time to time amongst them. One which Sir George Mackenzie mentions as being particularly active when he visited the island in 1809, and whose eruption Sir John Stanley describes as incessant, is now, by Mr Barrow's account, extinct; and the surface of the neighbourhood has been so totally altered, that it is with difficulty the accounts of recent travellers can be made to coincide with those at the commencement of the century. It is admitted, however, that the phenomena they all exhibit are occasioned by the production and confinement of steam in cavities, so formed, that when the accumulation arrives at a certain point, the pressure of the water opposing its escape is overcome, and the water is thrown out before it. The siliceous incrustations which are formed around the brim of the basin, and along the edge of the streamlets running out of it, are not the least remarkable productions of the Geyser. They consist of little tufts or knobs, grouped in such a manner as to bear a resemblance to the heads of cauliflowers; of so delicate a texture, however, that it is almost impossible to remove them in a perfect state. This deposit is principally formed from the condensed steam or vapour. The sides of the tube and the bottom of the basin, on the contrary, are, doubtless from the constant friction of the water, perfectly smooth, and as hard as agate.

Another very remarkable hot spring is the mud volcano of Reykialid, near Myvatn, towards the north-eastern extremity of the island. This occupies the crater of Mount Krabla, one of the principal volcanoes of Iceland, and is thus described by Henderson, who made the circuit of the island during the year 1815. "At the bottom of a deep gulley lay a circular pool of black liquid matter, at least three hundred feet in circumference, from the middle of which a vast column of the same black liquid was erupted with a loud thundering noise. This column is equal in diameter to that ejected by the Great Geyser at its strongest eruptions. The height of the jets varies greatly, rising on the first propulsions of the liquid to about twelve feet, and continuing to ascend, as it were, by leaps, till they gain the highest elevation, which is upwards of thirty feet, when they again abate much more rapidly than they rise; and after the spouting ceases, the situation of the aperture is rendered visible only by a gentle ebullition, which distinguishes it from the general surface of the pool; the eruptions take place every five minutes, and last about two minutes and a half." In the same vicinity are the hot springs of Husavik, which, though they bear no comparison in magnificence to those of Skalholt, are extremely interesting in many respects. The pipe of one of them, the Oxahver, which is said to have derived its name from the circumstance of an ox having fallen into it, is about eight feet in diameter, is surrounded with a strongly incrusted brim, and shortly below the surface trends to one side, and becomes quite irregular. Its jets rarely exceed twenty feet in height, but, according to Henderson's account, they are conducted with the utmost regularity in point of time. It was amongst the beautiful incrustations formed around the basin of this spring that Mr Rose of Edinburgh, during his mineralogical excursion a few years ago, observed that variety of apophyllite, to which the synonyme of Oxahverite was subsequently applied.

Though it cannot be denied that these springs have some communication with the volcanoes which abound in the island, yet it is a remarkable fact that they are seldom found very near them, although dispersed throughout the whole country. They possess unequal degrees of heat, ranging from 188° to 212°, and are generally devoid either of taste or smell, although the flavour of sulphur is occasionally perceptible. When their situation suits, they are turned to good account by the inhabitants, both as bathing quarters, and for various culinary purposes, in boiling fish, evaporating sea-water, and the like. At Reikholt there is a celebrated bath of this description, which was constructed six hundred years ago by the famous Snorro Sturleson. It is fourteen feet in diameter and six feet deep, being supplied, by means of covered conduits, both with hot and cold water, from springs about a hundred yards distant, so that any desired temperature might be obtained.

The contents of the Geyser water Dr Black ascertained to be, in 10,000 grains, or about one sixth of a gallon, of watcr,

Soda	0·95 gr.
Alumina	0·48
Silica	5·40
Muriate of soda	2·46
Dry sulphate of soda	1·46
Total	10·75

Geology. Though Iceland has been visited at different periods by several scientific men, little is comparatively known either of its geology or its mineralogy. To Sir George Mackenzie the world is indebted for a pretty minute description of the mineral products of the south-western portion of the island;[1] but of the east coast, which has long been celebrated for its magnificent zeolites and splendid calcedonies, little has as yet been made public. The island, from one extremity to the other, exhibits undoubted demonstrations of volcanic origin; immense tracks of lava, extensive beds of tuff, basaltic columns, greenstone, and amygdaloid, appear in succession at every step. The surfaces of some of the lavas which Sir George Mackenzie observed in Iceland he describes as not unlike coils of ropes or crumpled cloth; in other respects they appear to resemble the lavas of recent volcanoes elsewhere, being, like those of Ætna, thrown up into large flattened masses. These, it is well known, are produced by the formation of a crust on the lava during its course, which, as it accumulates, breaks through the hardened surface; and thus, when it cools, leaves a wide extended plain of the most rugged and impassable description. In some places the surface has swelled during the course of the lava into knobs, from a few feet in diameter to forty or fifty, many of which have burst, and disclose caverns lined with melted matter in the form of stalactites. Of these some remarkable instances are mentioned amongst the extremely rugged lava of Buderstad, in the vicinity of the Snaefell Yokul, where several of the caverns extend to the depth of forty yards. Stappen, in the same part of the island, presents, for the extent of about two miles, the most striking columnar appearances, both in the cliffs which form the shore, and in the numerous insulated rocks which appear at different distances from the land. In general, the ranges of columns assume a vertical position, and an elevation of about fifty feet; but in some places

[1] The Museum of the Royal Society of Edinburgh is enriched by an extremely interesting suite of minerals, collected by Sir George Mackenzie in this part of Iceland, and presented by him to the Society.

Iceland.

they are disposed indiscriminately upon one another in bundles, and in several instances appear diverging from a centre. Sir John Stanley describes a cavern on this coast which his party rowed into, as more curious even than the cave at Staffa; the columns, which were very lofty, diverging considerably from the roof towards the base. Frequently these columnar basalts are associated with or imbedded in tuffa, a volcanic production of the most universal occurrence. "Lava and tuffa," says Sir George Mackenzie, "are sure indications of each other. The mountains of the Guldbringé Gyssel are almost entirely composed of tuffa. The hills round Mount Hecla, near the Snaefell Yokul, and in the neighbourhood of every lava I met with, consist of that substance; in fact, it appears to be the predominant rock." Amygdaloid forms the larger portion of the eastern extremity of the island, and it is imbedded in this that those splendid specimens of calcareous spar *par excellence* denominated Iceland-spar are found. This rock is likewise the matrix of all the different varieties of the zeolite tribe, of the magnificent calcedonies, and in fact of most of the fine minerals which have long rendered Iceland so celebrated a locality among collectors. Fossilized wood is found in several places; that variety termed Surturbrand is peculiar to the north-eastern volcanic district. It is remarkable that the specimens hitherto brought home of this last substance appear to be oak. It burns with flame, and can be cut and shaped like jet; but from its brittleness does not admit of being sliced into shavings. Pumice, obsidian, and other volcanic minerals appear in great beauty in many districts of the island, particularly near Hecla, and to the north of Krabla.

Zoology.

There is little remarkable in the zoology of Iceland. The only wild animals are foxes, which in some parts of it are very numerous, and do much damage to the farmers in destroying their lambs and other produce. Rein-deer were introduced from Sweden about the middle of last century, and have since increased and run wild. The Iceland horse is small, but hardy, active, and capable of sustaining considerable fatigue. Dogs and cats they have in abundance, and rats and mice are proportionally numerous. The floating ice occasionally transports a polar bear or two from the Greenland coasts during spring, which, however, are no sooner heard of than the neighbouring country are up in arms to kill them, and they are consequently hunted down and destroyed without mercy. The skins of the foxes, particularly those of the blue species, are valued as an article of commerce.

Amongst the land-birds of the island are the sea-eagle or erne, a very destructive bird among the eider-ducks; the falcon, which used formerly to be a valuable item in the exports of the island; and the raven, which is a larger and more powerful bird than those of Britain, frequently pouncing upon and carrying off young lambs, and destroying poultry; it is met with in great numbers, particularly on the cliffs near the sea-coast. The ptarmigan, snipe, golden plover, wagtail, and curlew, are well known. Water-fowl of every description, common to northern latitudes, are met with on the coasts and in the lakes. Of these the most valuable to the inhabitants is the eider-duck, which is strictly preserved, a penalty of half a dollar being exigible for shooting one of these birds. From this circumstance they become so remarkably tame, especially in the breeding season, that they frequently make their nests close to the houses, and in spots which have been prepared by ridges of stones artificially built up for them; and in such places, during the process of incubation, it is not unusual for the female to remain on the nest, and suffer herself to be fondled. The lining of their nests, being the downy substance plucked off their own breasts, is taken away, even a second and third time, until the poor bird has plucked herself nearly naked. Their eggs, too, are removed once or twice, and are eaten in the same manner as plovers' eggs. Swans are very numerous in some of the lakes of the central part of the island, where they remain unmolested until the ice sets in, when they betake themselves to the sea-shore. The eggs, the feathers, and the down of this fine bird, like those of the eider-duck, supply the peasantry with an article of food, and also of commerce.

The vegetable productions of the island, as already stated, are the reverse of luxuriant. With the exception of a few stunted birch, rarely above six feet high, and some dwarf willows, in the southern and eastern districts, nothing in the shape of a tree occurs; and, even in the sheltered situations afforded by the gardens surrounding the merchants' houses near Reikiavik, all attempts to raise the most common culinary vegetables occasionally fail. Even in good years, Dr Hooker remarks that in many of these little enclosures the cabbages were so languid and small that a half-crown piece would have covered the whole of the plant. It is a curious fact, however, that timber has in former periods grown in more abundance, as is evident from the logs so frequently met with in the morasses and peat-bogs of the country. These the peasants are in the habit of extracting and using for fire-wood. The Surturbrand, already mentioned, has nothing to do with the antediluvian state of the island.

The scanty produce of the land is, however, to a great degree compensated for by the abundance of fine fish which occurs on the coast. In several parts of the island, particularly on the north and north-west, the shark fishery is a regular occupation. Strong hooks fastened to chains are baited and anchored a little way out to sea, and the fish when caught are thus towed to shore. Of the skin shoes are made, a considerable quantity of oil is extracted, and some parts of the flesh are occasionally smoked and used by the natives for food. The cod is very plentiful; the haddock grows to a large size; ling, skate, flounders, and halibut are likewise very common; the herring, too, frequents the fiords in vast shoals, but this branch of the fishery has hitherto been little attended to. The salmon in the rivers are said to be very fine, and no country in the world produces them in greater quantity. Seals are particularly numerous on the shores of the Breide-fiord and the western coast.

Such is a rapid sketch of the most remarkable features of Iceland. The ardour, however, with which the sciences of natural history and geology are now pursued in Britain, coupled with the increasing facility every year afforded by means of steam navigation, will no doubt, in the course of a very few summers, present us with more minute and more accurate information respecting the truly extraordinary natural productions of this wild but wonderful island.

(See *Letters on Iceland*, by Von Troil, in 1772; *Travels in Iceland*, by Sir George Mackenzie, in 1810; *Journal of a Residence in Iceland during the Years* 1814 *and* 1815, by Ebenezer Henderson; and *Visit to Iceland in the Summer of* 1834, by John Barrow, Esq. Jun.)

ICENI, the ancient name of the people of Suffolk, Norfolk, Cambridgeshire, and Huntingdonshire, in England.

ICHNOGRAPHY, in perspective, the view of any thing cut off by a plane parallel to the horizon, just at the base of it. The word is derived from the Greek ἰχνος, *footstep*, and γραφω, *I write*, as being a description of the footsteps or traces of a work. Amongst painters it signifies a description of images or of ancient statues of marble and copper, of busts and semibusts, of paintings in fresco, mosaic works, and ancient pieces of miniature.

ICHNOGRAPHY, in *Architecture*, is a transverse or horizontal section of a building, exhibiting the plot of the whole edifice, and of the several rooms and apartments in any storey, together with the thickness of the walls and partitions; the dimensions of the doors, windows, and chimneys; and the projectures of the columns and piers, with every thing visible in such a section.

ICHOR properly signifies a thin watery humour like serum, but is sometimes used for a thicker kind flowing from ulcers, called also *sanies*.

ICHTHYOCOLLA, Isinglass, a preparation from the fish known by the name of *huso*. The word is Greek, formed of ἰχθυς, *fish*, and κολλα, *glue*. The method of making isinglass was long a secret in the hands of the Russians. The following account of it was published by Mr Humphrey Jackson, in the 63d volume of the Philosophical Transactions.

"All authors who have hitherto delivered processes for making ichthyocolla, fish-glue, or isinglass, have greatly mistaken both its constituent matter and preparation. To prove this assertion, it may not be improper to recite what Pomet says upon the subject, as he appears to be the principal author, whom the rest have copied. After describing the fish, and referring to a cut engraved from an original in his custody, he says, 'As to the manner of making the isinglass, the sinewy parts of the fish are boiled in water till all of them be dissolved that will dissolve; then the gluey liquor is strained, and set to cool. Being cold, the fat is carefully taken off, and the liquor itself boiled to a just consistency, then cut to pieces and made into a twist, bent in form of a crescent as commonly sold; then hung upon a string and carefully dried.'

"From this account, it might be rationally concluded that every species of fish which contained gelatinous principles would yield isinglass; and this parity of reasoning seems to have given rise to the hasty conclusions of those who strenuously vouch for the extraction of isinglass from sturgeon; but as that fish is easily procurable, the negligence of ascertaining the fact by experiment seems inexcusable.

"In my first attempt to discover the constituent parts and manufacture of isinglass, relying too much upon the authority of some chemical authors whose veracity I had experienced in many other instances, I found myself constantly disappointed. Glue, not isinglass, was the result of every process; and although, in the same view, a journey to Russia proved fruitless, yet a steady perseverance in the research proved not only successful as to this object, but in the pursuit to discover a resinous matter plentifully procurable in the British fisheries, which has been found by ample experience to answer similar purposes. It is now no longer a secret that the lakes and rivers in North America are stocked with immense quantities of fish, said to be the same species with those in Muscovy, and yielding the finest isinglass; the fisheries whereof, under due encouragement, would doubtless supply all Europe with this valuable article.

"No artificial heat is necessary to the production of isinglass, neither is the matter dissolved for this purpose; for, as the continuity of its fibres would be destroyed by solution, the mass would become brittle in drying, and snap short asunder, which is always the case with glue, but never with isinglass. The latter, indeed, may be resolved into glue with boiling water; but its fibrous recomposition would be found impracticable afterwards, and a fibrous texture is one of the most distinguishing characteristics of genuine isinglass.

"A due consideration that an imperfect solution of isinglass, called *fining* by the brewers, possessed a peculiar property of clarifying malt liquors, induced me to attempt its analysis in cold subacid menstruums. One ounce and a half of good isinglass, steeped a few days in a gallon of stale beer, was converted into good fining, of a remarkable thick consistence; the same quantity of glue, under similar treatment, yielded only a mucilaginous liquor, resembling diluted gum-water, which, instead of clarifying beer, increased both its tenacity and turbidness, and communicated other properties in no respect corresponding with those of genuine fining. On commixing three spoonfuls of the solution of isinglass with a gallon of malt liquor, in a tall cylindrical glass, a vast number of curdly masses became presently formed, by the reciprocal attraction of the particles of isinglass and the feculencies of the beer, which increasing in magnitude and specific gravity, arranged themselves accordingly, and fell in a combined state to the bottom, through the well-known laws of gravitation; for in this case there is no elective attraction, as some have imagined, which bears the least affinity with what frequently occurs in chemical decompositions.

"If what is commercially termed *long* or *short stapled isinglass* be steeped a few hours in fair cold water, the untwisted membranes will expand, and re-assume their original beautiful hue,[1] and, by a dexterous address, may be perfectly unfolded. By this simple operation we find that isinglass is nothing more than certain membranous parts of fishes, divested of their native mucosity, rolled and twisted into the forms above mentioned, and dried in open air.

"The sounds or air-bladders of fresh-water fish in general are preferred for this purpose, as being the most transparent, flexible, delicate substances. These constitute the finest sorts of isinglass; those called *book* and *ordinary staple* are made of the intestines, and probably of the peritoneum of the fish. The belluga yields the greatest quantity, as being the largest and most plentiful fish in the Muscovy rivers; but the sounds of all fresh-water fish yield, more or less, fine isinglass, particularly the smaller sorts, found in prodigious quantities in the Caspian Sea, and several hundred miles beyond Astracan, in the Wolga, Yaik, Don, and even as far as Siberia, where it is called *kle* or *kla* by the natives, which implies a glutinous matter; it is the basis of the Russian glue, which is preferred to all other kinds for its strength.

"The sounds, which yield the finer isinglass, consist of parallel fibres, and are easily rent longitudinally; but the ordinary sorts are found composed of double membranes, whose fibres cross each other obliquely, resembling the coats of a bladder; hence the former are more readily pervaded and divided with subacid liquors; but the latter, through a peculiar kind of interwoven texture, are with great difficulty torn asunder, and long resist the power of the same menstruum; yet, when duly resolved, are found to act with equal energy in clarifying liquors.

"Isinglass receives its different shapes in the following manner: The parts of which it is composed, particularly the sound, are taken from the fish while sweet and fresh, slit open, washed from their slimy *sordes*, divested of every thin membrane which envelopes the sound, and then exposed to stiffen a little in the air. In this state they are formed into rolls about the thickness of a finger, and in length according to the intended size of the staple. A thin membrane is generally selected for the centre of the roll, round which the rest are folded alternately; and about half an inch of each extremity of the roll is turned inwards. The due dimensions being thus obtained, the two ends of what is called *short staple* are pinned together with a small wooden peg; the middle of the roll is then pressed a little downwards, which gives it the resemblance of a heart-shape; and thus it is laid on boards, or hung up in the air to dry. The sounds which compose the long

[1] If the transparent isinglass be held in certain positions to the light, it frequently exhibits beautiful prismatic colours.

Ichthyocolla.

staple are longer than the former; but the operator lengthens this sort at pleasure, by interfolding the ends of one or more pieces of the sound with each other. The extremities are fastened with a peg, like the former; but the middle part of the roll is bent more considerably downwards, and, in order to preserve the shape of the three obtuse angles thus formed, a piece of round stick, about a quarter of an inch diameter, is fastened in each angle with small wooden pegs, in the same manner as the ends. In this state it is permitted to dry long enough to retain its form, when the pegs and sticks are taken out, and the drying completed; lastly, the pieces of isinglass are colligated in rows, by running pack-thread through the peg-holes, for convenience of package and exportation.

"The membranes of the *book* sort, being thick and refractory, will not admit a similar formation with the preceding; the pieces, therefore, after their sides are folded inwardly, are bent in the centre, in such manner that the opposite sides resemble the cover of a book, from whence its name; a peg being run across the middle, fastens the sides together, and thus it is dried like the former. This sort is interleaved, and the pegs run across the ends, the better to prevent its unfolding.

"That called *cake-isinglass* is formed of the bits and fragments of the staple sorts, put into a flat metalline pan, with a very little water, and heated just enough to make the parts cohere like a pancake when it is dried; but frequently it is overheated, and such pieces, as before observed, are useless in the business of fining. Experience has taught the consumers to reject them.

"Isinglass is best made in the summer, as frost gives it a disagreeable colour, deprives it of weight, and impairs its gelatinous principles; its fashionable forms are unnecessary, and frequently injurious to its native qualities. It is common to find oily putrid matter, and *exuviæ* of insects, between the implicated membranes, which, through the inattention of the cellarman, often contaminate wines and malt liquors in the act of clarification. These peculiar shapes might probably be introduced originally with a view to conceal and disguise the real substance of isinglass and preserve the monopoly; but, as the mask is now taken off, it cannot be doubted to answer every purpose more effectually in its native state, without any subsequent manufacture whatever, especially to the principal consumers, who hence will be enabled to procure sufficient supply from the British colonies. Until this laudable end can be fully accomplished, and as a species of isinglass more easily produceable from the marine fisheries may probably be more immediately encouraged, it may be manufactured as follows:

"The sounds of cod and ling bear great analogy with those of the *accipenser* genus of Linnæus and Artedi, and are in general so well known as to require no particular description. The Newfoundland and Iceland fishermen split open the fish as soon as taken, and throw the backbones with the sounds annexed in a heap; but previous to incipient putrefaction, the sounds are cut out, washed from their slimes, and salted for use. In cutting out the sounds, the intercostal parts are left behind, which are much the best; the Iceland fishermen are so sensible of this, that they beat the bone upon a block with a thick stick, till the pockets, as they term them, come out easily, and thus preserve the sound entire. If the sounds have been cured with salt. that must be dissolved by steeping them in water before they are prepared for isinglass; the fresh sound must then be laid upon a block of wood, whose surface is a little elliptical, to the end of which a small hair-brush is nailed, and with a saw-knife the membranes on each side of the sound must be scraped off. The knife is rubbed upon the brush occasionally, to clear its teeth; the pockets are cut open with scissars, and perfectly cleansed of the mucous matter with a coarse cloth; the sounds are afterwards washed a few minutes in lime-water, in order to absorb their oily principle, and lastly in clear water. They are then laid upon nets to dry in the air; but if intended to resemble the foreign isinglass, the sounds of cod will only admit of that called *book*, but those of ling both shapes. The thicker the sounds are, the better the isinglass, colour excepted; but this is immaterial to the brewer, who is its chief consumer.

"This isinglass resolves into fining, like the other sorts, in subacid liquors, as stale beer, cider, old hock, and the like, and in equal quantities produces similar effects upon turbid liquors, except that it falls speedier and closer to the bottom of the vessel, as may be demonstrated in tall cylindrical glasses; but foreign isinglass retains the consistency of fining preferably in warm weather, owing to the greater tenacity of its native mucilage. "Vegetable acids are in every respect best adapted to fining; the mineral acids are too corrosive, and even insalubrious, in common beverage.

"It is remarkable, that during the conversion of isinglass into fining, the acidity of the menstruum seems greatly diminished, at least to taste, not on account of any alkaline property in the isinglass, probably, but by its enveloping the acid particles. It is likewise reduced into jelly with alkaline liquors, which indeed are solvents of all animal matters; even cold lime-water dissolves it into a pulpous *magma*. Notwithstanding this is inadmissible as fining, on account of the menstruum, it produces admirable effects in other respects; for, on commixture with compositions of plaster, lime, &c. for ornamenting walls exposed to vicissitudes of weather, it adds firmness and permanency to the cement; and if common brick-mortar be worked up with this jelly, it soon becomes almost as hard as the brick itself; but for this purpose it is more commodiously prepared by dissolving it in cold water acidulated with vitriolic acid, in which case the acid quits the jelly, and forms with the lime a *selenitic* mass, while, at the same time, the jelly being deprived in some measure of its moisture, through the formation of an indissoluble concrete amongst its parts, soon dries, and hardens into a firm body; whence its superior strength and durability are easily comprehended.

"It has long been a prevalent opinion, that sturgeon, on account of its cartilaginous nature, would yield great quantities of isinglass; but, on examination, no part of this fish, except the inner coat of the sound, promised the least success. This being full of *rugæ*, adheres so firmly to the external membrane, which is useless, that the labour of separating them supersedes the advantage. The intestines, however, which in the larger fish extend several yards in length, being cleansed from their mucus and dried, were found surprisingly strong and elastic, resembling cords made with the intestines of other animals, commonly called *catgut*, and, from some trials, promised superior advantages when applied to mechanic operations."

ICHTHYOLOGY.[1]

INTRODUCTORY CHAPTER.

Introduction.

SECT. I.—DEFINITION AND GENERAL OBSERVATIONS. THE PRINCIPAL EPOCHS IN THE SCIENCE OF ICHTHYOLOGY.

FISHES may be technically defined as *vertebrated animals with red blood, breathing through the medium of water by means of branchiæ or gills.* This definition, as Baron Cuvier has remarked, is the result of observation; it is a product of analysis, or what is termed in physics an empyrical formula; but its accuracy is demonstrable by the inverse method, for, when once duly perceived, we may in a great measure deduce from it a knowledge of the entire nature of the beings to which it is applied. Being vertebrated, they must be possessed of an internal skeleton; of a brain and spinal marrow, enclosed in a vertebral column; of muscles exterior to the bones; of four extremities only; and of the organs of the first four senses, situate in the cavities of the head; with other relations not necessary to be here named.

The greater portion of the surface of the earth is covered by the waters of the translucent sea; and wherever continents and the larger islands protrude their rocky bulk, we find them coursed by flowing rivers, or intersected by lakes and marshes. These present in their aggregate an enormous mass of waters, and afford protection and nourishment to myriads of living creatures, probably superior in number, and in no way inferior in beauty, to those which inhabit the earth. On land, the matter susceptible of life is mainly employed in the construction and continuance of vegetable species; from these herbivorous animals draw their nourishment; and this being animalized by assimilation, becomes an appropriate food for the carnivorous kinds, which scarcely amount to more than one half of the terrestrial creatures of all classes. But in the liquid element, and more especially among the saline waters of the ocean, where the vegetable kingdom is so much more restricted, almost all organized substances are pervaded by animal life, and each lives at the expense of some smaller or feebler foe. There we meet not only with the greatest and most wonderful variety of forms, but also with the extremes in respect to size,—from the myriads of microscopic monads, which, but for artificial means, must have remained for ever invisible and unknown, to the ponderous whale, which surpasses by twenty times the bulk of the largest elephant. There, too, we may discover the majority of those magnificent combinations of organic structure, on the relations of which naturalists have established the distinction of classes, or great primary groups,—in other words, the sea may be said to contain representatives of each; for, even among birds, those aerial creatures which usually inhabit so light an element, we find species so constructed as to dwell almost for ever on its waves. The mammiferous class is still more fully represented in the numerous tribes of seals, morses, manaties, and whales, all of which require a moist abode, and some of which immediately perish when deprived of it. Most reptiles are aquatic, many insects are so, more particularly in their larva state; and almost all the Mollusca, the Annelides, the Crustacea, and Zoophytes,—four great classes, which on terra firma are few and far between,—exist in countless numbers in the waters of the ocean. Hence that ancient dictum recorded by Pliny, " Quicquid nascatur in parte naturæ ulla, et in mari esse; præterque multa quæ nusquam alibi."

But amongst all the teeming wonders which vivify the vast expanse and liquid depth of waters, none so predominate, or are so truly characteristic, as the subjects of our present treatise; nor are any more worthy of our devoted consideration, whether we regard the beauty or eccentricity of their forms, the metallic splendour of their colours, or the innumerable benefits which, through the foresight of Providence, they confer upon the human race. We therefore deem it incumbent upon us to exhibit an ample view of the present condition of Systematic Ichthyology; but before doing so, we shall endeavour to add to the interest of the subject by a few general observations.

We may state, in the first place, that we here intentionally refrain from any bibliographical inquiry, or historical exposition of the progress of Ichthyology. If such were complete, or even ample, it would occupy too much of that space which we deem more usefully devoted to the actual condition of our subject-matter. We more willingly set that department aside, when we consider how perfectly it has been presented by Baron Cuvier.[2] We shall, however, briefly allude to what may be regarded as the principal epocha in the progress of Ichthyological Science. During many remote ages it consisted, in common with all the kindred branches of human knowledge, of nothing more than a few partial and disjointed observations. Aristotle, about 350 years before the Christian era, made some progress towards connecting these together as a body of doctrine; but still it was a feeble body, reposing upon truths (perceived indeed with surprising skill when we consider the scanty data) as yet obscurely known and vaguely expressed, owing to the entire absence of all proper standards for the distinction of species. For more than eighteen hundred years ensuing, those who wrote on natural history can scarcely be regarded in any other light than as either copiers or commentators of Aristotle; but about the middle of the sixteenth century, Belon, Rondelet, and Salviani, the true founders of modern Ichthyology, made their appearance (we mean as authors), by a singular coincidence, almost precisely at the same time,—the first in 1553, the second from 1554 to 1555, and the third from 1554 to 1558. Differing from their compiling predecessors, they

---

[1] From ἰχθυς, *a fish*, and λογος, *a discourse*.

[2] See the *Tableau Historique des Progrès de l'Ichtyologie, depuis son origine jusqu'à nos jours*, in the first volume of his great though unfortunately uncompleted work, the *Histoire Naturelle des Poissons.* We deem ourselves fortunate beyond our predecessors in encyclopædic labour, in having as a guide in so difficult a subject as that on which the reader is about to enter, the first nine volumes of Baron Cuvier's signal publication. We should act unwisely were we to present a crude compendium of the works of foreign and British writers, such as has hitherto sufficed for publications similar to that in which we are now engaged. We prefer adhering throughout to Cuvier's system of arrangement, as one which, without doubt, is entitled to supersede all others hitherto proposed. We shall also avail ourselves, wherever our doing so seems likely to instruct the reader, of whatever general or miscellaneous information is scattered through his work, presenting it in a form and sequence the most advantageous to those unacquainted with the voluminous original; and adding, especially in relation to our native species, whatever we find of interest in recent authors, among whom, as elucidators of " British Fishes," Messrs Couch and Yarrell stand pre-eminent. We beg to make this general acknowledgment of the infinite advantage we have derived from Baron Cuvier's labours, in the formation of the present treatise, in reference both to our introductory and systematic portions.

Introduction.

saw and examined for themselves, and made drawings from nature, if not with the elegant accuracy of modern days, at least with a recognisable exactness. Yet, true to the genius of their time, they continued to attach much more importance to the ascertainment of the names which the species bore in the classical pages of antiquity, than to the composition of their history, as it were afresh, by the light of nature and their own knowledge. Nevertheless they rectified as well as extended the observations of Aristotle, and laid a positive base or new foundation of the subject, by figures and descriptions of a certain number of well-determined species. About the close of the seventeenth century, Willughby, and his illustrious friend John Ray, gave for the first time a history of fishes, in which the species were not only clearly described from nature, but distributed in accordance with characters drawn solely from their structure, and in which we are no longer unnecessarily burdened with inapplicable passages from either Greek or Roman writers. Finally, about the middle of the eighteenth century, Artedi and Linnæus completed what the others had commenced, by establishing well-defined generic groups, consisting of ascertained species precisely characterised. From that period it may be said that no radical defect existed, nor any obstacle in the way of a gradual perfecting of the system, which could not be overcome by zeal, accuracy, and perseverance. Nevertheless it is to the genius of Baron Cuvier that we owe the gigantic stride which has been made in our own more immediate days. Prior to 1815, the methods of almost all the modern systematic writers were little else than modifications, variously disguised, of the Linnæan system,—that is, with alterations, generally for the worse, of the nomenclature of the illustrious Swede. They darkened knowledge by a multiplicity of vain words;—and when any principle of classification was brought forward,—if new, then it was untrue to nature,—if true to that beautiful abstraction, then it was already familiar as household words. But forty years assiduously devoted to Ichthyology,—that is, to a deep study of all preceding authors, to a constant ascertainment of whatever could be gathered of the habits of fishes, and to the formation of an unrivalled museum of comparative anatomy, where both their outward and internal forms were perfectly displayed,—convinced the great French naturalist that many heterogeneous groups still formed portions of our ichthyological system, and that a salutary reformation might consequently be effected in numerous minor details.

It was obvious, from an attentive consideration of the subject, that the differences of both external and interior organs, by which fishes might be distinctly characterised, were not less numerous than decided; and that in truth there were few classes of created beings among which it was more easy to recognise the existence of natural groups. But with a view to dispose of the genera and families in a becoming order, it was necessary to seize upon a small number of important characters, from which might result certain great divisions, not likely to break up natural relations, and yet sufficiently precise and perceptible to leave no doubt as to the place of each species. This was a principal desideratum, and one which the industry and perseverance, not less than the genius and high attainments, of Cuvier, have gone so far to satisfy.

The numerous characters held in common by the chondropterygian or cartilaginous fishes were too remarkable to have escaped detection by those who loved and sought for the light of system. Thus all Ichthyologists have agreed in the formation for these fishes of a separate order; but the Baron has observed, that almost all have likewise injured the justness of their ordinal division, by a combination of certain species which resembled the true cartilaginous kinds merely in the softness of their skeleton. Thus the genera *Lophius* and *Cyclopterus*, except in that softness, do not differ in any respect from the ordinary osseous fishes, and therefore ought not to be withdrawn from them. But there are others which, in addition to the softness of their bones, present peculiar characters in their tegumentary system, in their teeth, and especially in the disposition of the skeleton of the head, which render their immediate union with either of the great groups of osseous or cartilaginous fishes a matter of greater doubt and difficulty. Such, for example, are the genera *Tetrodon*, *Diodon*, *Ostracion*, and *Balistes*. The *Syngnathi*, or pipe-fish, likewise present, in their peculiar branchiæ, distinctive characters of great importance. The remarkable external aspect of these different genera had long induced the majority of naturalists to separate them from the others; but it so happened also that the same majority were by no means fortunate in discovering the true characters of separation. Thus Artedi not only re-united them to the *Lophii* and lump-fish, in the order of branchiostegous fishes, but he established that entire order on a false supposition—to wit, that they possessed no rays in their branchial membrane ("*branchiis osseis, ossibus destitutis,*"—"*branchiostegi in branchiis nulla ossicula gerunt,*"[1])—while the fact is, that they all possess those rays, and that even Artedi himself has inadvertently described both their nature and their number (*membrana branchiostega ossicula sex gracilia continet*) in his notice of the lump-fish (*Cyclopterus*) in question.[2]

Linnæus,[3] after placing the chondropterygian fishes among the reptiles, and adding thereto the genus *Lophius*; after referring the *Mormyri* and *Syngnathi* to the branchiostegous fishes of Artedi, and assigning to them the character of wanting not only the rays of the branchiæ, but the opercula (the contrary in several species being obvious to the most simple observation); afterwards combined[4] the Chondropterygii and Branchiostegi into a single order of *reptiles* (*Amphibia Nantes*), on the supposed but quite erroneous basis of their being possessed at once of lungs and gills. Gmelin re-established the two orders of Artedi, but still attributing to the Branchiostegi the absence of rays. Gouan characterised them merely by the incompleteness of their branchiæ,—a vague expression, and indeed contestable in almost all the genera. Pennant combined them with the Chondropterygii, under the common name of *Cartilaginous*, a term adopted by M. Lacépède; but which Cuvier has shown, in relation to the actual contents of the group, to be improper. The great French anatomist has observed that the appellation is by no means applicable, either in a positive or a negative sense. It cannot in any way be maintained that the skeleton of the *Balistes* is cartilaginous; and among the number of species which Pennant and his followers leave among the osseous fishes, there are several, for example, the *Leptocephali*, in which we can scarcely perceive the vestige of a skeleton.[5]

Baron Cuvier's great object thus became, to disentangle, as it were, those anomalous groups, or at least to separate all such as seemed to differ sufficiently from the type of ordinary fishes to authorize such separation. His next object was the discovery of precise characters, capable of being clearly expressed in words. This examination soon convinced him that such genera as *Lophius*, *Cyclopterus*, *Centriscus*, *Mormyrus*, and *Macrorhynchus*, had been erroneously withdrawn from the great group of ordinary

Introduction.

fishes, from which in fact they essentially differed in nothing. But he satisfied himself that the singular genus *Syngnathus*, of which the form and economy are so remarkable, were distinctively characterised by their branchiæ, in the form of tufts (hence the title of *lophobranchial* fishes), concealed beneath an opercle which permits the water to escape only by a small opening towards the nape of the neck; and that the genera *Diodon*, *Tetrodon*, *Ostracion*, and *Balistes*, independently of the singularity of their general form, and the incompleteness of their skeleton, have the jaws, and in general all the bones of the head, somewhat differently arranged from the corresponding parts in the generality of fishes, the upper jaw and the palatine bones being articulated with each other, and with the vomer, by immoveable sutures—a structure which leaves them much less freedom in the opening of their mouths, and is also the cause (in connection with the tightness of the tegumentary envelope which fastens down the branchial apparatus) of so many naturalists having failed to perceive that the genera in question were furnished with rays and opercula like other species.

But these groups once separated, there remained nine tenths of the whole class of fishes, among which the first great distinctive division which presents itself is, into such as have soft fins, or of which the rays are branched and articulated, and into such as have spiny fins, of which a portion of the rays consist of pointed bones without branches or articulation,—two primary divisions, corresponding to the great groups named respectively Malacopterygii and Acanthopterygii by Artedi. Even this principle of classification is not universally prevalent; for, in its practical application, we are obliged to keep out of view the first rays of the dorsal and pectoral fins in certain species of the genera *Cyprinus* and *Silurus*, in which these rays exhibit strong and solid spines, although we still class them with the Malacopterygii, or soft-finned division.[1] In like manner, there are, among the other great division, corresponding exceptions to the acanthopterygian character, as in the blennies and certain Labridæ, of which the spines are so small, so feeble, or so few in number, as almost to escape detection. However, if the principle referred to is not quite precise in relation to these slight anomalies, it is on the whole well founded, and certainly does not force us to separate numerous species which nature has approximated.

The same cannot be asserted of those distinctions which naturalists have sought to establish on other principles, nor of those on which so many of the secondary divisions have been founded. Thus the general form of the body, and the absence of the ventral fins, the characters assumed by Ray, anterior to those deduced from the spines, force a heterogeneous grouping of the eels, the gobies, the Syngnathi, the Xiphias, and the moon-fish. Linnæus was the first (in the tenth edition of the *Systema Naturæ*), while neglecting the distinction of the spiny rays, to imagine the division of ordinary fishes into *apodal*, *jugular*, *thoracic*, and *abdominal*, according to the absence or position of the ventral fins; and in so doing obliged himself to place the genera *Xiphias*, *Trichiurus*, and *Stromateus* with the eels and *Gymnoti*, the *Gadi* between the weevers and the blennies, *Pleuronectes* between *Zeus* and *Chætodon*, and the *Amphacanthi* as intermediate with *Silurus* and *Loricaria*. Various modifications have since been proposed of the Linnæan arrangement, but our present limits will not admit of our entering upon these as exhibited in the various works of Gouan, Lacépède, Dumeril, Risso, Rafinesque, Goldfuss, Oken, and others who have laboured to amend the modern system.[2]

SECT. II.—THE EXTERNAL FORM AND CHARACTER OF FISHES.[3]

The form and structure of fishes are as admirably adapted for rapid movement through the water, as are those of birds for that aerial motion called flight. Suspended in a liquid element of almost equal specific gravity with themselves. external organs resembling those of birds in size would have been disproportioned and unnecessary; but the air-bladder (the functions of which, by no means entirely understood, have never been satisfactorily explained in all their bearings) is known to possess the power of contraction and dilatation, the exercise of which is followed by a corresponding descent or ascent of the animal's body. Thus a small, central, and inconspicuous organ effects, in the easiest and most simple manner, the same object which even the soaring eagle or giant condor can only attain by great exertion of the wings, and after laborious and frequently repeated gyrations. We shall ere long, however, have occasion to observe, that the air-bladder, although essential to the economy of such species as possess it, is by no means indispensable to the class of fishes, as in many tribes it is entirely wanting.

Fishes being without a neck, and the part called the tail for the most part equalling at its origin the portion of the trunk from which it springs, the prevailing shape is somewhat uniform, diminishing gradually towards either end. Doubtless, however, a vast variety of form is exhibited in a class which is now calculated to contain from six to eight thousand collected species. Of these forms a sufficiently accurate idea may be acquired by inspecting the numerous plates which accompany the present treatise, and we shall therefore not attempt any further verbal illustration of the subject, although we shall add a few notices regarding the general aspect and character of the principal external parts.

The mouth of fishes either opens from beneath, as in the rays, or at the extremity of the muzzle, as in the majority of the class, or from the upper surface, as in *Uranoscopus*. It also varies greatly in its relative dimensions, from the minute perforation of *Centriscus*, to the vast expansion of the angler fish.

Exteriorly only two of the organs of the senses are visible, the orifices of the nostrils and the eyes. The former may be simple, as in the rays and sharks, or double, as in the generality of osseous fishes; and they differ in their position in relation to the jaws, the eyes, or the extremity of the muzzle. The eyes vary extremely in respect to size in the different species, and even sometimes disappear entirely beneath the skin; and they also differ greatly in their position, being usually placed laterally, one on each side of the head, although in *Uranoscopus* (as the name implies) they look upwards, and in most of the flat fishes they both occupy the same side.

In regard to those important organs, the branchiæ or gills, a single family alone, the chondropterygian fishes,

[1] These spines, however, as Cuvier remarks, are formed, in the two genera above named, by the agglutination of a multitude of smaller parts, of which the articulations, though not obvious, are perceptible.

[2] For critical notices of their works, see the 1st volume of the *Hist. Nat. des Poissons.*

[3] We may here premise, that in the ensuing sections several interesting and important particulars in the structure and physiology of fishes are very slightly, or even not at all, touched upon, in consequence of their having been already detailed in the article Comparative Anatomy of this work. (See vol. iii. p. 1, &c.) We deemed it more advisable that the reader should be made to incur the slight inconvenience of referring occasionally to a separate treatise, than that the present publication should be burdened by a repetition of the same subject.

Introduction.

are characterised by having their exterior margin fixed to the skin, with as many openings for the issue of the water as there are intervals between the branchiæ themselves; but all other fishes have the external margin of the branchiæ free, and the water which enters the mouth escapes by the opening of the gill-covers.

A certain number of the fins are vertical, and serve the fish somewhat in the same way as a vessel is served by her helm and keel. Of these, some, called *dorsal*, are attached to the back, others, beneath the tail, are named *anal*, while a fine expansion, which usually terminates the body, is known as the *caudal* fin. All these are *vertical* fins, and vary in different tribes, either in number, or dimensions, or the nature of the rays by which they are supported, and which are sometimes spiny, sometimes branched and composed of numerous articulations. The other fins are disposed in pairs, and represent the four external members of the higher classes, such as quadrupeds and birds. Those which correspond to the fore-legs of quadrupeds and the wings of birds are named the *pectoral* fins, and are always attached behind the gills; those again which are regarded as the analogues of the hinder extremities of the other classes are named the *ventral* fins, and have a considerable range of position in different species, from as far forward as beneath the throat, to the origin of the tail. Like the vertical fins, they also vary in size, and in the number and structure of their rays; and one or even both pairs are occasionally wanting, as in eels, which have no ventral fins, and Murenæ, which have neither ventral nor pectoral fins. Indeed the *Apterichti* have no fins at all.

Those fishes are named MALACOPTERYGIAN, of which all the rays of the fins are articulated, and of a softer structure; while such as are characterised by having at least a portion of their rays hard, simple, and in the form of spines, are included under the general title of ACANTHOPTERYGIAN fishes.[1] These great divisions apply solely to the osseous species. We have already mentioned that the cartilaginous kinds are distinguished by the name of CHONDROPTERYGIAN, while two lesser groups, in some respects intermediate between these and the preceding, fall under the orders LOPHOBRANCHII and PLECTOGNATHI of Baron Cuvier.

The differences hitherto alluded to are connected with intimate structure—with the skeleton or bony frame-work of the fish. There are of course others of a slighter or more superficial character. The jaws may be armed with teeth of all sorts, and these weapons sometimes occupy all parts of the mouth, and are found occasionally even in the throat. The lips are frequently furnished with a kind of fleshy beard or barbles, which differ greatly in number, size, and substance. Some have long fleshy isolated filaments hanging to the body, as in *Scorpæna;* and occasionally one or more of the rays is to a certain extent detachable from the fin, and susceptible of independent movement.

The nature of the surface or external tegument of fishes also varies greatly. Some may be called naked, while others are scaly, spinous, or plated, in whole or in part. If to these considerations we add the infinitely varied character of colour in all its admirable distributions, and the differences in size and weight observable in fishes, we shall be able to form a general idea of the external aspect of this great and important class.

SECT. III.—THE OSTEOLOGY OF FISHES.

In regard to the texture of the bones of fishes, their skeletons are either *bony*, *fibro-cartilaginous*, or *truly cartilaginous.* Those distinguished by the last-named character are the chondropterygian groups, such as the sturgeons, sharks, and rays, all of which exhibit throughout the whole of their frame-work, in their branchiæ (the external border of which is fixed to the skin, and through which the water is allowed to escape only by narrow openings), and in other important parts of their organization, distinctive characters, which obviously separate them from all other fishes. They are in fact destitute of true bones, their harder parts consisting only of a homogeneous and semitransparent cartilage, which is merely covered on the surface in certain genera by a layer of small, opake, calcareous granules, closely set together. In the lampreys even this envelope is wanting, while among the *Ammocœtes* the skeleton continues in an actually membranous condition. The sturgeons and Chimeræ partake in some measure of the lamprey character in relation to the softness of their spines, but the first-named genus is possessed of many true bones of the head and shoulder.

Other fishes differ in their osteological character chiefly in the hardness of their skeleton, and it is without reason that the fibro-cartilaginous kinds have been associated by some authors with the Chondropterygii. The calcareous matter, that is, the phosphate of lime, is deposited in layers and fibres in the cartilage which forms the basis of their bones, precisely in the same manner as among the hard-boned species, but less abundantly; and the texture of the bone never becomes so hard and homogeneous as among the osseous kinds. Thus in *Tetrodon Mola* we perceive, as it were, only scattered fibres amid the membranes, and in *Lophius piscatorius* they are nearly as soft. The other Tetrodons and Diodons, the Balistes and the Ostracions, have denser bones; and in some species these parts can scarcely be distinguished from those of the osseous fishes. It is certain also that the bony frame-work of the fibro-cartilaginous kinds is constructed on the same plan as that of the truly osseous species, and not in accordance with those of the Chondropterygii; and it is in opposition to the known truth of nature that both Artedi and Linnæus have denied them the possession of opercula and branchiostegous rays. The *Balistes* have even ribs,—their only osteological difference consisting in the granulation of their jaws; while the *Syngnathi* have regular bony jaws, although they want the ribs and branchiostegous rays.

The majority of osseous fishes have bones fully harder than those of other animals, and it is quite a gratuitous assumption to suppose that the observed longevity of certain species arises from the softer consistence of those parts. Certain fish bones, in fact, exhibit neither pores nor fibres, and appear almost vitreous to the eye. But neither the osseous nor the cartilaginous kinds have either epiphyses to the bones, or medullary canal within them; but there are some, such as the trouts, in which the tissue of the bones is more or less penetrated by an oily juice; while in others, such as the Dory, the internal portion continues cartilaginous, while the surface is completely ossified. Finally, in certain species, while the general skeleton is very hard, particular portions of it are cartilaginous. Such are the bones which constitute the head of the pike.

When viewed in relation to their general structure, the bones of fishes, like those of other vertebrated animals, are composed of an organic base penetrated by earthy matter. The latter consists of phosphate of lime and of magnesia, with oxide of iron, supposed to be united to phosphoric acid. There is also a certain portion

[1] It may be here noted, however, that certain malacopterygian kinds, such as carps and siluri, have the articulations of some of the rays soldered together, in such a manner as to appear simply spinous.

of subcarbonate of lime. The animal matter is of two kinds:—the one, of an azotised nature, forms the base of the cartilage; the other is fatty, in the form of a pervading oil. The cartilage of fish bones differs from that of mammiferæ and birds, in as far as it yields no gelatine when subjected to the process of boiling. The oil is composed chiefly of oleine, impregnated with an odorous principle and a yellow colouring matter. The oil itself is easily convertible into soap, and then produces oleic acid, glycerine, and a minute portion of margaric acid.

The skeleton of osseous fishes consists of the head; of the respiratory apparatus, having always a large bony development; of the trunk, including body and tail; and of members, that is, the pectoral and ventral fins. The vertical fins, viz. those of the back, anus, and tail, may likewise be viewed as belonging to the trunk.

The head, possessing many more moveable parts than that of the Mammalia, is subdivisible into a great many regions, such as the cranium, the maxillæ, the bones beneath the cranium and behind the jaws, and which aid in their movement and suspension; the bones of the opercles, which open and shut the overtures of the branchiæ; the bones, almost exterior, which surround the nostrils, the eye, and the temples, or which cover a portion of the cheek.

In the majority of fishes the inter-maxillary bone forms the edge of the upper jaw, and has behind it the maxillary, commonly called the mystax, or labial bone. A palatine arch, composed of the palatine, of the two pterygoid processes, of the jugal, tympanic, and squamous bones, constitutes, as among birds and snakes, a kind of interior jaw, and provides posteriorly an articulation to the lower jaw, which has usually two bones on each side. In the Chondropterygii, however, these various pieces are greatly reduced in number.

Besides the apparatus of the branchial arches, the hyoid bone carries on each side certain rays which support the branchial membrane; a kind of lid or clapper, composed of three bony pieces, the opercle, the sub-opercle, and the inter-opercle, unites with that membrane to close the great opening of the gills; it articulates with the *os tympani*, and plays on the piece called the pre-opercle. But, like the parts before mentioned, this apparatus is likewise wanting in many of the Chondropterygii.

The trunk is composed of the vertebræ of the back and tail (for we can scarcely say that there is any neck, and the sacrum is wanting); of ribs; of the interspinal bones, which give support to the dorsal and anal fins; and of the rays of those fins, and of the caudal. These rays, whether branched and articulated, or simply spinous, may be always divided lengthways into halves.

The vertebræ of fishes are characterised by the conical hollow on each of their faces. Double hollow cones are thus formed in the interval between two vertebræ, filled by a soft membranous and gelatinous substance, which passes from one void to another by means of an opening through each vertebra, and forms as it were a gelatinous chaplet through the whole. They have, as in other animals, an annular portion in their superior part, for the passage of the spinal marrow.

Fish rarely possess a sternum properly so called, and when it does exist, it is formed of almost external pieces, which unite the inferior extremities of the ribs.

The anterior members, commonly called the pectoral fins, consist of the shoulder, an osseous semicircle composed of several bones suspended above from the cranium or the spine, and joined beneath to the corresponding portion of the other side. We can here also distinguish certain bones analogous to the two pieces of the omoplate of reptiles, to the humerus, and to the bones of the fore-arm; and further back there is usually a small projection, composed of two pieces, which have been supposed to represent the coracoid bone, and even the clavicle. What is more assured is, that the two bones which Cuvier compares to the cubitus and radius, bear on their margin a range of little bones, which seem to represent those of the carpus, and which themselves support the rays of the pectoral fin, excepting the first of the latter, which articulates directly with the radial bone.

The posterior members, much more variable in their position than the corresponding limbs of the Mammalia, and of which the external and moveable portions are named the ventral fins, project sometimes in advance of, sometimes beneath, and sometimes behind, the anterior or pectoral members. They are composed of four bones, of which the largest, which are likewise the most constant, being always placed in advance of the anus and of the generative system, may be regarded as a sort of pubis, and bear upon a portion of their posterior margin the rays of the fin, without any smaller intermediate bones which can be compared either to the femur, the tibia, the peroneum, or tarsal bones. The rays of both the pectoral and ventral fins are likewise divisible lengthwise into halves, like those of the vertical fins before mentioned. These rays, with the exception of the external ventral one of the *Acanthopterygii* (which is spinous), are almost always articulated.

The skeleton of the *Chondropterygii*, such as sharks and skates, is composed of pieces consisting of no fibrous tissue characteristic of bone. The interior continues in a cartilaginous state, and the surface alone becomes indurated by the accumulation of small calcareous granules, which produce externally a *stippled* aspect. The form of the cranium is similar to that of other fishes, but nevertheless consists of only one enclosure, without sutures. The face is very simple, with only two bones in the palato-temporal arch;—the first descending from the cranium, at the articulation of the jaws,—the other representing the upper jaw, and bearing the teeth. The maxillary and inter-maxillary bones are merely rudimentary. The under jaw has also but one bone (the articular) on each side, bearing the teeth; of the others only a single vestige is discoverable, concealed beneath the skin of the lip. The opercular apparatus is wanting, but the hyoidean and branchial structure is very conformable with the same parts in osseous fishes. Sharks have, moreover, opposite to the external attachment of each branchia, a slender bone, which may be regarded as the genuine vestige of a rib. The branchial system is situate further back than in osseous fishes, and hence the humeral girdle is also more posterior. The spinal ribs, if they exist, are usually very small, except in the sturgeons. In that genus, indeed, the branchial system is in some respects intermediate between the cartilaginous and osseous fishes. Several bones of the head and shoulder are as hard as stone, yet the spine is almost as soft as that of lampreys.[1]

---

[1] For the sake of a more explicit comprehension of the principal portions of the osteological system of fishes, we have figured (from Cuvier) the skeleton of the perch. We shall here subjoin the names of the bones, in reference to the engraved numerals. See Plate CCXCVII. figs. 1, 2, 4, 5.

Cranium: Principal frontal, 1; anterior frontals, 2; ethmoidal, 3; posterior frontal, 4; basilary, 5; sphenoid, 6; parietals, 7; inter-parietal, 8; external occipital, 9; occipital lateral, 10; great ala, or temporal ala, 11; mastoidean, 12; rupes, 13; orbitary ala, 14; anterior sphenoid, 15; vomer, 16. *Upper jaw:* Inter-maxillary, 17; maxillary, 18. *Nasal, sub-orbitary, and supra-temporal bones:* First sub-orbitary, 19; chain of bones attached to the last named, and ending at the posterior frontal (these are conspicuous in Trigla and Scorpæna), likewise numbered 19; nasal, 20; supra-temporals, 21. *Palatine arch*, or *palatino-pterygoidean* and

SECT. IV.—THE MUSCLES AND MUSCULAR MOTIONS OF FISHES.

The spinal column, composed of numerous articulations united by cartilages which permit of certain movements, curves with great facility from side to side; but the vertical motion is much more restricted, chiefly in consequence of the projection of the upper and under spiny processes of the vertebræ.

The great organ of movement in all fishes is the tail. The muscles by which it is brought into play extend in lengthened masses on either side of the vertebral column. The body being supported chiefly by the swimming bladder (which, however, is absent in several species), is pro-

temporal system: Palatine, 22; temporal, 23; transverse bone, 24; internal apterygoidean, 25; jugal, 26; tympanal, 27. *Opercular bones:* Operculum, 28; styloid, 29; pre-operculum, 30; sympletic, 31; sub-operculum, 32; inter-operculum, 33; this last-named bone furnishes an attachment to the branch of the hyoid bone at the point where it is itself joined to the styloid, which suspends it on the temporal bone, and hence the opercular shutters can neither open nor close without a corresponding movement of the hyoidean branches. *Lower jaw:* Dental, 34; articular, 35; these are the usual divisions, but there is often a third bone, the angular, 36, and sometimes a fourth, on the internal face of the articular, corresponding to the opercular of reptiles, 37. Thus the head of fishes usually consists of about sixty bones—the amount being sensibly greater in such species as have the upper maxillary subject to division.

Hyoid bone and branchiostegous rays. The three opercular pieces above mentioned do not of themselves effect the closure of those great clefts observable on each side of a fish, between the head and shoulder, and within which are the respiratory organ sor branchiæ. This closure is completed by the *branchiostegous membrane,* which adheres to the hyoid bone. (See Plate CCXCVII. figs. 2, 4, and 5.) This bone is placed as in other vertebrated classes, but is always suspended to the temporal bones. It is composed of two branches, each consisting of five pieces, viz. the styloid, 29, by which it is suspended to the temporal; two large lateral pieces, 37 and 38, placed one behind the other, and forming the principal portion of the branch (the posterior, 38, being that which attaches to the inter-operculum); lastly, two small pieces, 39 and 40, placed one above the other at the anterior extremity of the branch, and serving to unite it with the corresponding portion of the other side. Anterior to this junction is the lingual bone, 41, and behind it, in the angle formed by the meeting of the two branches, and beneath the branchiæ, is a single piece, usually vertical, 42 (fig. 5), which represents the tail of the hyoid bone, so well known in birds and lizards. It is this piece which, uniting with the symphyses of the humerals, forms what is called the *isthmus,* which separates the two branchial openings from below. Thus in its totality the hyoid bone of fishes is composed of twelve bones.

The *rays,* 43, which support the branchiostegous membrane, adhere by moveable articulation, or by simple ligaments, to the inferior margin of the principal portions already mentioned (37, 38) of the hyoid bone. They vary in form and number, some species having three, others thirty. The perch, which forms the subject of our illustration, has seven branchial rays; and that number is the most common among the acanthopterygian fishes.

Bones which support the branchiæ. As fishes cannot respire except by making the water which they have taken into the mouth flow out by the openings behind the lateral part of the head, it thus passes between the branchiæ, those well-known comb-like organs, usually four in number on each side, composed of a great quantity of thin, narrow, forked laminæ, of a membranous or cartilaginous nature, and placed in files. These four pair of branchiæ are supported by four pair of arches, adhering by their inferior extremities to the two sides of a chain of small intermediate bones, which is itself attached to the angle formed by the anterior portions of the hyoid bone, and above the *tail* of the latter. These arches ascend in a curve, and are attached at their other extremity beneath the cranium, but by means only of cellulosity, or of ligaments. The intermediate chain of bones just alluded to forms, in a certain sense, a continuation of the lingual bone. There are usually three: the first, 53 (see chiefly fig. 4), is attached at the base of the angle formed by the two branches of the hyoid bone; the second, 54, affords attachment to the first pair of arches; and the third, 55, affords the like attachment to the second pair, while the third pair adheres to its extremity; the fourth pair of arches is connected with the angle of the third pair. Each arch is composed of two parts, moveable on each other, and the inferior portion of the first three pair itself consists of two pieces, 57 and 58; in the last pair there is only a single piece, 60. The upper portion of the arches, 61, is simple, except in the first pair, which is usually suspended from the cranium by a small stylus, 59. The inner face of these arches is furnished with small plates or cones of osseous lamina, usually armed with teeth variously disposed according to the species. The most general uses of this armature are to arrest the progress of such substances as the fish is swallowing,—to prevent their escaping with the respired water, or their producing inconvenience amid the interstices of the branchiæ. It may be likened in its functions to the epiglottis of quadrupeds, or the dentations of the margins of the larynx of birds. Besides the interior range of conical plates, the perch possesses an external row of slender pointed teeth, resembling those of a garden rake, upon its first pair of arches, see 63.

Pharyngeal bones. At the entrance to the œsophagus, and immediately below the branchial apparatus, are placed the pharyngeal bones, which produce a second mastication, often more powerful than the first; for this purpose they are armed with teeth of very variable form and number, according to the species. These bones are usually two inferior, 56, and six superior, 62.

Vertebræ. We have already described the general character of the vertebral bones of fishes. Their special forms will be best understood by an inspection of Plate CCXCVII. fig. 1, Nos. 67, 68, 69, with the processes, marked *a, b, c.* The *ribs* are shown at 72; the styles or appendages which frequently adhere to those parts, at 73. In a few fishes the ribs are entirely wanting.

Vertical fins. These are supported by rays composed of an internal portion, named the interspinal, 74, which serves as a sustaining root, by penetrating the flesh among the great lateral muscles, and an external portion, which exhibits the rays *properly so called,* as seen at 75. We sometimes find an interspinal bone which bears no rays, 76. A certain number of these vertical rays are pointed bones, and are then named spines, or spiny rays; others are bony or solid only towards their base, their remainder being formed of a multitude of small articulations, and frequently ramified into lesser branches, themselves still further divided; in these states they are named articulated, soft, or branched rays. Those of the tail, 71, are always soft and articulated; although, towards the root, both above and below, 78, they gradually diminish till only the solid portion of the base remains. In a great number of fishes the vertebra at which the abdomen terminates and the caudal part begins, and even that which follows it, 83, 83, have a great inferior spinous process, to which is joined a more or less voluminous bone, 79, extending behind the anus, and thus forming the posterior boundary of the abdominal cavity.

The *sternum* does not exist in all fishes. When present, it consists of a series of single bones of various configuration, according to the genera, and at these the ribs terminate.

Bones of the shoulder and arm. In osseous fishes, we find on each side, immediately behind the orifice of the gills, a suite of bones, forming a kind of frame, on which the opercle rests when closed. These bones, usually attached to the head from above, and uniting together below, form an osseous belt, surrounding that part of the body. Their inferior symphysis unites by ligaments to the tail of the hyoid bone (formerly mentioned, 42), and forms with it the *isthmus,* which separates the external openings of the gills from each other beneath, just as the cranium separates them above. This cincture, when complete, is composed on each side of three bones, which represent the shoulder and the arm, to which adheres, posteriorly, a group of two or three others, occupying the place of the fore arm, and bearing the pectoral fin, which may be considered as the hand; lastly, there is almost always suspended a style, composed of one or two bones, which Cuvier regards as the analogue of the coracoidian bone. The highest of these first three bones, 46, is usually forked, and attached by its two crests to the lateral crests of the cranium. It is visible externally at the top of the branchial opening, resembling a scale, larger than the others, and is sometimes toothed on its edges. The second, 47, continues along the margin of the branchial opening. The third, 48, always the largest, completes the cincture, by uniting with its counterpart beneath the throat. To the inner surface of the last-mentioned bone adheres a fourth, 51, and fifth, 52, placed one above the other. The free side of these bones bears the pectoral fin, but by means of an intermediate range of four or five small bones, 53. These bonelets may be supposed to represent the carpal series; and if so, then the two others, 51 and 52, will be the cubitus and radius. The third pelled forwards by the rapid flexure of the extremity acting laterally upon the resistance offered by the water. Generally speaking, neither the pectoral nor the ventral fins are of any material use during swift progressive motion; they rather serve to balance the body, or to aid its gentler movements while in a state of comparative repose. In *flying fishes*, as they are called, the pectoral fins are of such great length and expansion as to support the animal in the air; and the strength of muscular action might probably suffice even for a longer flight, but for the necessity of constant moisture for the purposes of respiration. The drying of the gills in an individual of this class is attended by results analogous to those produced by submersion in the case of a land animal;—and a flying fish is obliged to descend to respire, in like manner as a swimming quadruped, or disguised mammiferous animal (as we may term a whale), is under the necessity of ascending for the same purpose.

The head of fishes exercises but a slight movement independent of the rest of the body; but the jaws, hyoid bone, palato-temporal and branchial arches, and pharyngial and opercular bones, are very free in their motions. The muscles of fishes, like those of other vertebrated animals, are composed of fleshy fibres more or less coloured, and of tendinous fibres of a white or silvery colour. With the exception, however, of certain special muscles which are sometimes of a deep red, the flesh of fishes is much paler than that of quadrupeds, and still more so than that of birds. In some species it is even entirely white.

SECT. V.—THE NERVOUS SYSTEM AND SENSES OF FISHES.

The sensitive system of fishes, like that of the higher classes, is composed of the external senses, of a central medullary apparatus, and of nerves of communication. As in the classes alluded to, the central portion of the nervous system, that is, the brain and spinal marrow, occupies the cavity of the cranium and vertebral column.

As fishes respire through the intervention of water alone, that is, as they can scarcely avail themselves, in rendering their blood *arterial*, of any thing more than the small portion of oxygen contained in the air which is suspended in the water, their blood is necessarily cold, and their general energy, and the activity of their senses and movements, are less than among Mammalia and birds. Their brain also, though of similar composition, is proportionally much smaller; and the external organs of the senses do not seem of such a nature as to be capable of impressing or conveying towards it any vivid excitement. Indeed the most striking characteristic of the brain of fishes is its extreme smallness, when compared either with the total size of the body, with the mass of nerves which proceed from it, or with the cavity of the cranium in which it is contained. In the burbot, or *Gadus lota*, the weight of the brain to that of the spinal marrow is estimated by Carus to be as 8 to 12, and to that of the whole body as 1 to 720. It was previously known that the brain of the pike weighed in proportion to that of the whole body as 1 to 1305. Now, in many small birds, the brain, viewed in relation to the rest of the body, is equal to a twentieth part. In the generality of fishes, the spinal marrow extends along the whole of the caudal vertebræ; and it is thus that it preponderates over the brain. The *Lophius piscatorius*, however, and a few other species, form remarkable exceptions to this rule, as in them the spinal marrow disappears before it reaches the eighth vertebra; but in the greater proportion of cases it may be said that the spinal cord in this class terminates by a single thread in the last caudal vertebra.[1] The brain of fishes by no means fills up the cavity of the cranium; and the interval between the pia-mater which envelopes the brain itself, and the dura-mater, which lines the interior of the skull, is occupied only by a loose cellulosity, frequently impregnated by an oil, or sometimes, as in the sturgeon and thunny, by a rather compact grease. It has also been remarked, that this void between the cranium and the brain is much less in young subjects than in adults; from which it may be inferred, that the brain does not increase in an equal proportion with the rest of the body. Cuvier, in fact, has found its dimensions nearly the same in different individuals, of which the general size of the one was double that of the other.

When compared with that of quadrupeds, the brain of fishes has been said to possess an embryonic character, and to have its greatest development in the cerebellum, the seat of the appetites. Of all vertebrated animals, fish in fact exhibit the smallest apparent signs of sensibility. Having no elastic air to act upon, they are necessarily mute, or nearly so; and all the sensations which the delightful faculty of voice has called into being among the higher tribes, are to them unknown. Their glazed immoveable eyes, their fixed and bony faces, their bodies and members moving altogether, if they move at all, admit of little play in their physiognomy, and of scarcely any expression to their emotions. Their ears, surrounded on every side by the bones of the cranium, destitute of external conch, without any internal cochlea, and composed merely of some sacks and membranous canals, scarcely suffice for the perception of the loudest sounds. Even their sight may be supposed to find but little exercise in those profound depths where so many of the inhabitants of ocean dwell, although the largeness of the visual organs in many species probably in some measure makes amends for this deficiency of light. But even in those species the eye cannot change its direction; still less can it alter its focus, so as to accommodate the vision to a varying distance; for the iris neither dilates nor contracts, and the pupil remains for ever the same in all degrees of light. No tear moistens its glazed surface, no eyelid clears or protects it, and it

---

bone of the cincture, which supports the two last named, will then necessarily represent the humerus, and the first and second (46–7) the shoulder blade. There still remains to be mentioned a species of style, almost always composed of two pieces, 49 and 50.

Carpal bones. At the outer edge of the radial and cubital bones adhere the small flat bones, 53, compared to the carpus. Their function is to support the rays of the pectoral fin, 53, *a*, however numerous these may be, with the exception of the first, which articulates directly with the radius or upper bone, 52.

Bones of the hinder extremity. The os innominata, the thigh, the tibia, and the tarsus, are represented in fishes by a single bone, 80, usually of a triangular form, but more or less complicated by processes and projecting plates. Its posterior side affords attachment to the rays of the ventral fins. In eels and others, in which the ventral fins are wanting, the bone is also absent.

The rays of the extremities. These rays, that is, those of the pectoral and ventral fins, 82 and 53, *a*, without being as symmetrical as those of the vertical fins, are equally divisible into halves. Except the external ray of the ventral in the Acanthopterygii, 81, they are almost always articulated, but their bases become solid, and there the articulation is scarcely if at all perceptible.

[1] In regard to the shortness of the spinal cord in *Lophius*, the fact, as above referred to, is taken from the dissertation of Apostolo-Arsaki, a Greek doctor, who published *De piscium cerebro et medulla spinali*, Halle, 1813; but in a note to the *Hist. Nat. des Poissons* of Cuvier (vol. i. p. 437), we find the following correction of that statement:—"Sa moelle règne presque tout le long de l'épine; mais elle est enveloppée et cachée par les nerfs, qui naissent beaucoup plus haut qu'ils ne sortent." It is certain, however, from Cuvier's recent statement, that the supposed character is truly exhibited by the *moon-fish* (*Lampris guttatus*, Retz; *opah* of Pennant), "Où la moelle épinière est tellement raccourcie qu'elle ne semble qu'une petite proéminence conique de l'encéphale, de laquelle les différentes paires de nerfs partent comme une queue de cheval." (*Ibid.*)

Introduction.

consequently offers but a dull and feeble representative of that beautiful and most expressive organ, so full of life and animation in the higher tribes.

The position, direction, and dimensions of the eyes of fishes vary greatly. In some they have an upward aspect, and are often very close upon each other; in others they are lateral, and so wide apart as to be even directed slightly downwards. But of all anomalies, one of the most extraordinary which their position presents, is that of the *Pleuronectes* (such as turbot, flounders, soles, &c.), in which the two eyes are placed, as it were, the one above the other, and both upon the same side of the head. In certain species of the eels and *Siluri*, they are so small as to be scarcely visible; while in other groups, such as *Priacanthus* and *Pomatomus*, they surpass in proportional diameter whatever is known of the same organs in the higher classes. It may be said in general that the eye of fishes is large, and that its pupil especially is broad and open; a character probably connected with the necessity of collecting whatever devious rays of light may penetrate the obscure depth of waters. Fishes have no true eyelids. The skin always passes over the eye, to which it is slightly adherent; and it is for the most part sufficiently transparent for the passage of the solar rays. In some species, such as eels, it passes over without the slightest fold or duplication; while in a few, for example, the *Gastrobranchus cæcus* of Bloch, it continues quite opake, so as entirely to conceal the eye. In others, as the well-known mackerel and herring, it forms an adipose fold both before and behind; but these folds are fixed, and being unprovided with muscles, have no mobility. Sharks have one, somewhat more moveable, on the inferior margin of the orbit. The globe of the eye itself is very slightly moveable, although, like that of man, it is furnished with six muscles. Perhaps the most singular eye presented by the class of fishes is that of *Anableps*, which has two corneæ, separated by an opake line, and two pupils pierced in the same iris, so that one might deem it double; but there is only one retina, and a single vitreous and crystalline humour. In accordance with the general structure of the eyes of fishes (which we shall not further detail), the nearly spherical form of the crystalline humour, the immobility of the pupil, and the difficulty with which it changes the length of its axis, we can scarcely doubt that the vision of this class is comparatively imperfect. Images must be but feebly painted in their retina, and their visual perceptions must be indistinct and dull. At the same time it is evident that they perceive their prey from a considerable distance; and the angler, who knows either how rapidly they seize or how cautiously they avoid his lure, and with what discrimination they sometimes prefer one colour or kind of artificial fly to another, must be impressed with the belief that the power of vision, at least of certain species, is by no means devoid of clearness and precision.

The *organ of hearing* in fishes consists of little more than the labyrinth, and that a much less complicated one than the corresponding part in either quadrupeds or birds. They have no external ear, unless we may bestow that name on a small cavity, sometimes slightly spiral, which we find in the rays. It is however always covered by the skin, and is not perceptible among the osseous fishes. A few of the latter, such as the genus *Lepidoleprus*, and certain *Mormyri*, have merely openings in the cranium closed by the skin, by means of which the vibrations of the element by which they are surrounded may be conducted to the labyrinth. In some other species, as *Myripristis*, the cranium is open beneath, and its orifice is closed by a membranous partition, to which the swimming bladder adheres; but these communications are very different from that which takes place by means of the tympanum, and still more by means of the Eustachian tube in other classes. Both these parts, as well as the bones, are in fact wanting in the class of fishes. Those who find in the bones of the operculum the four bones of the ear of man suddenly and prodigiously developed, hazard such a notion merely on the assumption that the bony pieces are the same in number in all crania; but it must be borne in mind, that neither the form, nor the relations, nor the functions of these bones, nor their nerves nor muscles, support such a comparison. The ear of fishes, then, is much less complete than that of quadrupeds, birds, or even of the majority of reptiles. There is no doubt that they possess the sense of hearing; but it is merely a general sense of sound, and is in all probability incompetent to perceive any variety or range of intonation. In truth, the simple fact of fishes being as a class entirely mute, is of itself a logical ground for believing that their perception of sound is extremely dull.

A few lines may now be devoted to the consideration of the *sense of smell.* The nostrils of fishes are not so placed as to be traversed either by air or water, in connection with the act of respiration. They consist merely of two openings, situate near the extremity of the muzzle, and lined by the pituitary membrane, which is raised in extremely regular folds. In the ordinary fishes, the bones which Cuvier regards as the nasal serve as the arch or covering; while the vomer, the maxillary, and inter-maxillary contribute to sustain the sides, the first sub-orbitary forming the inferior portion. The shape of the nostrils is sometimes oblong, sometimes round or oval. They are placed either at the end of the muzzle or on its sides; sometimes on its superior face, and even occasionally, as in skates and sharks, on its under surface near the angle of the mouth. In the lamprey they are approximate on the top of the head, and open by one common orifice. In the great majority of fishes, perhaps in all the osseous kinds, each nostril opens by two orifices, the one posterior to the other, and in some cases at a considerable distance. These are what are called double nostrils; an inaccurate term, in as far as each pair of holes leads only to a single cavity. The margins of the anterior orifice are often tubular, as in the eel, and sometimes a single side of the tubular margin is prolonged into a tentacular appendage, as in several Siluri. In the genus *Lophius* the nostrils are borne upon a little pedicle, so as somewhat to resemble mushrooms. Various other modifications are observable in different genera, although not necessary to be here narrated. It does not appear, at least in the osseous fishes, that the envelope of the nostrils possesses mobility, or that the orifices are furnished with muscles by means of which they can be opened and shut.

It is certain, however, that fishes possess the faculty of perceiving odours; that various scents attract or repel them; and there is no reason to doubt that the seat of that perception lies in the nostrils. It may be reasonably conjectured that its strength depends mainly on the degree of development produced by the number and extent of the interior folds.

In regard to the *sense of taste* in fishes, it is evident that as, with few exceptions, they swallow their food rapidly and without mastication, their perception of that faculty must be in noways acute. The same may be inferred from the fact of their tongue being almost immoveable, often entirely osseous, or beset with teeth or dental plates, and from its receiving very slender nerves, and these but few in number. Even those species of which the jaws are so armed as to enable them to cut and bruize their aliments, cannot long retain the latter in their mouths, on account of the position and the play of the respiratory organs. No salivary glands discharge their moisture on the organs of taste. The tongue itself is not seldom entirely wanting; and even when it exists in its most distinct and apparently fleshy state, it consists merely of a ligamentous or cellular substance, applied on front of the lingual bone. It is never furnished with muscles capable of producing any movement of extension or retraction, as in quadrupeds.

Fishes cannot be said to be more highly favoured in respect to the *organs of touch* than those of taste. The faculty is greatly deadened over the general surface by the coating of scales, and in the particular members by the inflexibility of the rays. It is chiefly confined to the lips, and even these parts in many species are themselves as hard and insensible as bone. Certain soft and delicate appendages called *barbles*, possessed by many species, such as the cod and loach, are supposed to enjoy a more delicate perception of the sense of touch. It is by means of the *dermis* that that peculiar matter, so remarkable for its silvery metallic lustre, and which bestows so much of brilliancy upon the class, is secreted beneath the scales. It is composed of small polished plates resembling burnished silver, and capable of being removed by washing, either from the skin itself, or from the inferior surface of the scales. It is this substance that is used in the formation of false pearls. It is also secreted by many species in the thickness of the peritoneum, and in the envelopes supplied by that part to particular viscera, especially the swimming bladder. The scales of the majority of fishes are *imbricated*, that is, placed partially over each other, like the tiles or slates of the roof of a house. They are not equally distributed, nor of the same form or consistence, over the general surface of the body. The head is frequently destitute of scales, and those of the lateral line of the body are distinguished from the others by one or more small tubes by which they are perforated, and by other peculiarities.[1]

It thus appears that the external senses of fishes convey to them few lively or distinct impressions; and by whatever scenes in nature they are surrounded, their perceptions are probably indistinct and dull. Their sexual emotions, cold as their blood, indicate only individual wants. Few species pair, or enjoy any connubial gratification, for the males seek the eggs rather than the females which deposit them, and neither sex ever recognises its offspring. At least the exceptions to these generalities are extremely few, and the prevailing economy of fishes may be said in all these respects to be exactly the reverse of that of birds. These gay creatures of the sky have the power of surveying distinctly at a glance an immeasurable extent of horizon; their acute perception of hearing appreciates all sounds, and every intonation; and their glad voices are exquisitely skilled in their production. Though their bills be hard, and their bodies covered by down and feathers, they are by no means deficient in the sense of touch. They enjoy all the delights of conjugal and parental affection, and perform their incumbent duties with devotedness and courage; they cherish and defend their offspring, and will sometimes die in that defence; and of all the wonderful labours of instinctive art, none is so beautiful as the formation of their mossy dwellings. With what deep and continuous affection does the female brood over her cherished treasures! how unwearied is the gallant male in his tender assiduities, and in the rich outpouring of that varied song by which he seeks to soothe her sedentary task! The same principle of attachment and discrimination is even made available in a state of domestication by the skill of all-engrossing man. A bird acquires a knowledge of its master, and submits to and obeys that master's will; and the proud falcon, which in its natural state

> Doth dally with the wind, and scorn the sun,

will wheel in airy circles over a well-trained dog, or stoop its boldest flight at some familiar urchin's call. Other species will even imitate man's noblest faculty, the power of speech,—and it is thus with somewhat doubtful feelings that we deny to them the gift of reason.

But the silent dweller in the deep knows few attachments, expresses no language, cherishes no affections. Constructing no dwelling, he merely shelters himself from danger among the cavernous rocks of the ocean, or beneath the murky shade of the overhanging banks of rivers; and the cravings of hunger seem alone to exercise a frequent or influential action over his monotonous movements. We must not, however, suppose that the life of fishes is not one of enjoyment, for we know that the great Creator "careth for *all* his creatures;" and it ought perhaps rather to be said that we cannot appreciate the nature of their feelings, than that they are in any way fore-doomed to a negation of pleasure. Assuredly, however, the hand of nature has been most prodigal in bestowing on their external aspect every variety of adornment. Their special forms are infinite, their proportions often most elegant, their colours lively and diversified, and nothing seems wanting in them to excite the admiration of mankind. Indeed it almost appears as if this prodigality of beauty was intended solely for such an end. The brightness of metallic splendour, the sparkling brilliancy of precious gems, the milder effulgence of the hues of flowers, all combine to signalise fishes as among the most beautiful objects of creation. When newly withdrawn from their native element, or still gliding submerged in its liquid coolness, their colours, fixed or iridescent, are seen mingling in streaks or bands, or broader flashes, always elegant and symmetrical; sometimes richly contrasted, sometimes gradually softened into each other; and in all cases harmonizing with a chaste fulness of effect, which Titian or Rubens might envy, but could never equal. For what reason, then, it has been asked, has all this adornment been so lavishly bestowed on creatures which can scarcely perceive each other amid the dim and perpetual twilight of the deep? Shakspeare has already said that there are "more things in *heaven* and *earth* than are dream't of in our philosophy;" and we fear it is no answer to the foregoing question to add, that the same observation applies with even greater truth to the "*waters beneath the earth.*"

SECT. VI.—THE NUTRITION, MANDUCATION, AND DEGLUTITION OF FISHES.

The nutritive functions of fishes follow the same order of progression as those of the other vertebrated classes; they seize and in some measure divide their food with their teeth; they digest it in the stomach, from whence it passes into the intestinal canal, where it receives a supply of bile from the liver, and frequently a liquid similar to that of the pancreas; the nutritive juices absorbed by vessels analogous to lacteals, and probably taken up in part also directly by the veins, are mingled with the venous blood which is flowing towards the heart, from whence it is pushed to the branchiæ, in which, coming into contact with the water, it is converted into arterial blood, and then proceeds to the nourishment of the whole body. As in other animals, also, certain properties are carried off from the blood by transpiration, the secreting power of the kidneys, &c.

Fishes in general are extremely voracious, and the rule of "eat or be eaten" applies to them with unusual force. They are almost constantly engaged in the pursuit and capture of their prey; their degree of power in these respects depending of course on the dimensions of the mouth

[1] See *Hist. Nat. des Poissons*, t. i. chap. vi.

Introduction.

and throat, and the strength of the teeth and jaws. If the teeth are sharp and hooked, they are capable of securing the slenderest and most agile animals; if they are broad and strong, they are able to bruise the hardest aliment; if they are feeble or entirely wanting, they are only serviceable in procuring some inert or unresisting prey. Fishes indeed show but little choice in the selection of their food, and their digestive powers are so strong and rapid as to suffice to dissolve very speedily all kinds of animal substances. They greedily swallow other fishes, notwithstanding the sharp spines or bony ridges with which they may be armed; they attack and devour crabs and shell-fish, gulping them entire if they cannot otherwise attain their object; they do not object occasionally to swallow the young even of their own species, and the more powerful kinds carry their warfare into other kingdoms of nature, and revel on rats, reptiles, and young ducklings, to say nothing of the ferocious shark, which not seldom makes a meal even of the lord of the creation. The species which live chiefly on vegetable substances are few in number.

The growth of fishes depends greatly on the nature and supply of food, and different individuals of the same species exhibit a great disparity in their respective dimensions. They grow less rapidly in small ponds or shallow streams, than in large lakes and deep rivers.[1] The growth itself seems to continue for a great length of time, and we can scarcely set bounds to, certainly we know not with precision, the utmost range of the specific size of fishes. Even among species in no way remarkable for their dimensions, we ever and anon meet with ancient individuals, favourably situated, which vastly exceed the ordinary weight and measurement of their kind.

The teeth of fishes are sometimes spread over all the bones which envelope the cavities of the mouth and pharynx; on the maxillary, inter-maxillary, and palatine bones; on the vomer, the tongue, the branchial arches, and pharyngeal bones. In certain genera they exist on all those parts; while in others they are wanting on some, or are even entirely absent on all. The denominations of the teeth are derived from their position, that is, from the bones to which they are attached, and are consequently as numerous as the varieties of their situation. Their forms are not less varied than their stations, and give rise to terms still more numerous. The majority are conical or hooked, more or less acute. When these hooks are in considerable number, and disposed in several rows, or in quincunx, they are compared to those sharp points which beset the instruments called *cards,* used in the working of wool or cotton. It is to this form and distribution that we allude in the descriptive portion of the present treatise when we happen to use the French term *en carde.* Sometimes the teeth of fishes are slender, and so closely set together as to resemble to the eye the *pile* of velvet, in which case they are said to be *en velours*;[2] when they are at the same time extremely short and close, they are likened to smooth velvet; when feeble and elongated, they are said to be brushy or hair-like. Lastly, those kinds of teeth are sometimes so extremely small and short as to be reduced to mere asperities, sensible rather to touch than sight. The whole are simple, and spring from an equally simple pulpy germ.

In the majority of osseous fishes, besides the lips, which, even when fleshy, having no peculiar muscles, can exert but little strength in retaining the aliments, there is generally in the inside of each jaw, behind the anterior teeth, a kind of membranous fold or valvule, formed by a replication of the interior skin, and directed backwards, of which the effect is to hinder the alimentary substances, and especially the water gulped during respiration, from escaping again by the mouth. This structure, as formerly supposed, does not constitute a character restricted to the genus *Zeus*, but exists in an infinity of fishes. The food seized by the teeth of the maxillæ, and detained by the valve just mentioned, is carried still farther back by the teeth of the palate and tongue when these exist, and is at the same time prevented by the dentations of the branchial arches from penetrating between the intervals of the branchiæ, where it might injure the delicate organs of respiration. The movements of the maxillæ and tongue can thus send the food only in the direction of the pharynx, where it undergoes additional action on the part of the teeth of the pharyngeal bones, which triturate or carry it backwards into the œsophagus. The last-named part is clothed by a layer of strong, close-set, muscular fibres, sometimes forming various bundles, the contractions of which push the alimentary matter into the stomach, thus completing the act of deglutition.[3]

SECT. VII.—THE CIRCULATION OF FISHES.

Fishes, in common with warm-blooded animals, are provided with a complete circulation for the body, and with another equally complete for the organs of respiration, and with a particular abdominal circulation terminating at the liver by means of the vena porta; but their peculiar character consists in this, that the branchial circulation alone is provided at its base with a muscular apparatus or heart, corresponding to the right auricle and ventricle of the higher classes, while nothing of the kind exists at the base of the circulating system of the body; in other words, the left auricle and ventricle are entirely wanting—the branchial veins changing into arteries without any muscular envelope.

The muscular apparatus of their circulation is composed of the auricle, the ventricle, and the bulb of the pulmonary artery, and the auricle itself is preceded by a large sinus, in which all the veins of the body terminate; a structure which gives rise to four cavities separated by restrictions, into which the blood must flow in its progress from the body to the branchiæ. Their size is small in proportion to the dimensions of the body, and does not increase in the same ratio with the growth of the individual. Three of these receptacles, the auricle, the heart, and the bulb, are lodged in a pericardium, which is itself placed beneath the pharyngeal bones, between the inferior parts of the branchial arches, and for the most part protected externally by the humeral bones. The great venous sinus is not placed in the pericardium, but between the posterior partition of that cavity and the membrane which represents the diaphragm,

Introduction.

[1] The writer of this treatise kept a minnow little more than half an inch long in a glass tumbler for a period of two years, during which time there was no perceptible increase in its dimensions. Had it continued in its native stream, subjected to the fattening influence of a continuous flow of water, and a consequent increase in the quantity and variety of its natural food, its cubic dimensions would probably have been twenty times greater; yet it must have attained, prior to the lapse of a couple of years, to the usual period of the adult state.

[2] The French expression of *dents en velours*, which so frequently occurs both in the *Règne Animal* and the *Hist. Nat. des Poissons*, is one of the many instances, as Dr M'Murtrie has remarked, in which Baron Cuvier's expressions bid defiance to all English synonyms.

[3] The various notices (as already intimated) of the internal structure of fishes contained in the article COMPARATIVE ANATOMY of this work (vol. iii.) absolve us from the propriety of presenting any details regarding the form and constitution of the intestinal canal, and of certain other important interior organs of the class.

Introduction.

and which is merely the anterior portion of the peritoneum strengthened by aponeurotic fibres. This sinus is extended transversely, and receives by several different trunks the veins of the liver, of the generative organs, of the kidneys, of the fins, branchiæ, and throat, and finally those of the head, which themselves partly pass by a sinus at the back of the cranium. The first-mentioned sinus sends the whole of this blood by a single orifice of its anterior convexity into the auricle, which receives it through the opening of its anterior portion. Two thin membranous valvules protect this communication, and are turned towards the auricle. The latter organ is placed in the pericardium, in front of the great sinus, and above the ventricle, that is, on its dorsal aspect. It presents very various and often remarkable configurations. In osseous fishes it is usually of a tetrahedral form,—in the cartilaginous kinds more frequently rounded and depressed. It is situate beneath the auricle, the cavity being so turned as to be almost vertical next that organ, and horizontal towards the bulb. Its coats are extremely robust, and furnished internally with powerful fleshy columns, its substance being composed of two different layers. But it is in the bulb of the branchial artery that we find the most vigorous fibres, usually disposed in a circular form. The prolongation of this bulb issues from the pericardium, and becomes the branchial artery, advancing forward beneath the single chain of small bones which unites the arches of the branchiæ. The branchial artery soon divides, and in such a manner as to send a branch to each branchia. These branches pass along a hollow groove on the convexity of each branchial arch, and more external than the vein which follows the same track, but in an opposite direction. To the arch are attached a great number of leaflets, parallel to each other, usually terminated in a forked point, and sometimes deeply divided. The principal branch which passes along the groove of the arch gives a smaller branch to each of the leaflets; and this branch, after being twice bifurcated, furnishes an infinity of lesser branchlets, which meander over the surface of each leaflet, till they are finally converted into extremely minute veins. These little vessels meet on each side in a branchial vein, which proceeds along the internal margin of the lateral lobe of the leaflet, and the two veins open into the trunk of the great vein of the branchia.

On passing out of the dorsal side of the branchia, the branchial veins assume the structure and functions of arteries; even before their arrival at this point, the anterior have already sent several branches to different portions of the head; and it is necessary to remark, that the heart and several parts situate in the chest receive their blood from a branchial vein, by means of an offset issuing from near its source, and consequently anterior to its exit from the branchiæ. Nevertheless, it is only by the re-union of the trunks proceeding from the four branchiæ that the great artery is formed which carries the blood to the viscera and all the parts of the trunk, and which is by consequence the representative of the aorta of the Mammalia,—but of an aorta which possesses neither auricle nor ventricle at its base. Thus, according to Cuvier's views, the left cavities of the heart of quadrupeds do not exist in fishes, but are replaced by a simple vascular apparatus, situate above the branchiæ, in like manner as the right cavities are placed beneath them.

SECT. VIII.—THE RESPIRATION OF FISHES.

It is thus by an almost infinite subdivision of the vessels over the surface of the branchiæ or gills, that the blood of fishes becomes subjected to the influence of an ambient fluid. This fluid is of course water, which is made to flow incessantly between the branchiæ by the movement of the jaws, and of the opercular and hyoidean apparatus. This mode of respiration is equally necessary to fishes, as the direct respiration of air is to other animals; but the action of water on the blood is much more feeble than that of air. It appears that it is neither the water itself, nor the oxygen contained in it, which effects the respiration, but the small portion of air which is held in solution or mingled with the water. If this is expelled by ebullition, fishes cannot live; and many species are obliged to rise frequently to the surface for the purpose of breathing atmospheric air. It is easy to suffocate various kinds, by keeping them beneath the surface, enclosed in a gauze net. In the respiration of fishes, as in that of other animals, both the atmospheric air and that contained in the water give out their oxygen. The absorption of the latter, however, is very trifling among these aquatics, for it has been calculated that a man consumes fifty thousand times more than is required by a tench. When fishes are deprived of water, they perish not so much for want of oxygen, as because their branchiæ become dry, and their blood can no longer circulate with freedom. Hence the species of which the branchial orifice is small, as the eel, or those which possess receptacles for moisture, like *Anabas* and *Ophicephalus*, long survive exposure; while such as have their gills greatly cleft and open, as the herring, expire almost instantly when withdrawn from their moist abode.

SECT. IX.—THE SWIMMING BLADDER OF FISHES.

One of the most remarkable and characteristic organs of fishes is the swimming bladder, commonly so called. In many genera it has no opening or external communication, and the air which it contains must therefore be the result of secretion. It is composed of an extremely fine internal tunic, and of another of a thicker texture and peculiar fibrous structure, remarkable for producing the finest kind of isinglass. It is enclosed within the general coating with which the peritoneum invests the other viscera. It is sometimes simple, as in perch, sometimes furnished with more or less numerous appendages, as in some of the haddock tribe, or branched, as in certain *Sciænæ*.[1] Occasionally we find it divided, as it were, into two parts, by a restriction, as in the genus *Cyprinus*, many of the *Salmonidæ*, and others. The *Catastomæ* have it even divided into three. It is chiefly among the abdominal fishes that we find it communicating by a tube or tunnel with the intestinal canal, and either directly with the œsophagus, as in *Cyprinus*, or with the base of the stomach, as in the herring. That of the sturgeon opens into the former portion by means of a large orifice. The contents of the swimming bladder are usually found to be azote, mingled with some fractional parts of oxygen or carbonic acid. A difference of opinion, however, seems to exist regarding the proportion of oxygen, which is estimated as much greater both by Configliachi and Biot. Some physiologists appear to have regarded the swimming bladder as a true lung, which both admitted and returned the external air; but in many species the air-duct which connects the bladder with the gullet is entirely wanting; and in many others which remain constantly at prodigious depths, the quantity of oxygen gas in the swimming bladder is greater than in those the abode of which is near the surface. Indeed the oxygen is said to increase in quantity in proportion to the depth at which the species dwells. Carus considers it probable that the vessel in question performs a part analogous

[1] For representations of various forms of the swimming bladder of fishes, see Plate CCXCVII. figs. 3, 6, 7, 8.

Introduction.

to that of the expiratory functions of the lungs in the higher classes, by not only separating excrementitious azote and superabundant oxygen from the blood, but even discharging those elements in such species as have this particular viscus provided with an air-duct.

The more obvious use, however, of this organ seems to be to maintain the fish in equilibrium, or to lighten or increase its relative weight, so as to cause an ascension or a sinking, in proportion as the bladder is compressed or expanded. This is probably effected by the contraction or dilatation of the ribs. At all events, it is certain, that when the air-bladder bursts, the fish remains at the bottom, usually turning up its belly, and exhibiting other irregularities in its locomotion. Another curious effect is observable in regard to fishes which have been suddenly brought from a great depth by means of a long fishing line, and which having no time either to compress or partially empty the organ in question, the air which it contains being no longer pressed by the heavy weight of water, either expands so as to burst the bladder, or by its dilatation forces the stomach and œsophagus into the fish's mouth. When the air-bladder is pierced artificially, the fish almost immediately turns upon its back, and sinks to the bottom.

We have already alluded to the physiological opinion which regards this organ as an auxiliary to the respiratory system, and have likewise adverted to the argument against that opinion, deduced from the fact of its being imperforate in many species, and entirely wanting in others. We may add, that Weber[1] has pointed out a remarkable connection between the swimming bladder and the organs of hearing. It would appear that the former in several instances subserves the latter as a membrana tympani; but its primary, or at least most important purpose, seems to be to regulate the ascending or descending movements. Though of the highest importance in the structure of such species as possess it (and these are by far the greater number), yet the swimming bladder is not indispensable in the general economy of the class of fishes. In several genera (*e. g. Pleuronectes*) it is entirely wanting, and the species in such cases generally remain at the bottom, and, swimming obliquely on one side, propel themselves forward by a nearly vertical motion of the tail. In such cases both eyes are on the same side, and the whole structure of the fish, especially the skeleton of the head, presents an unsymmetrical aspect of a very extraordinary kind.[2] In many cartilaginous fishes, such as rays (commonly called skates), the absence of the swimming bladder seems compensated by the enormous size of the pectoral fins, which, of all the external organs, are probably the most efficient in raising the body, as the caudal extremity is the power chiefly employed during an onward course. The lamprey, which has neither swimming bladder nor pectoral fins, dwells in the mud. Flat fishes being unprovided with swimming bladders, are supposed for that reason to raise themselves with difficulty to the surface; and they do not appear to strike the water laterally like other fishes, but swim rather after the manner of the Cetacea, by a motion alternately up and down. In all the other animals of this class the chief organ of progressive motion is the tail, or prolongation of the body, terminated by a caudal fin, the position of which, unlike that of the great aquatic mammalia called whales, is vertical. The reason of the difference is obviously this: A true fish, possessing the power of extracting air from water by means of its gills, does not (except at rare intervals) require to mount to the surface for the performance of the vital act of respiration; but all cetaceous animals being furnished with lungs, which cannot perform their functions except through an immediate communication with the atmosphere, require their bodies to be terminated by a horizontal expansion, the action of which is the most efficient for an ascending course.

It is, however, difficult to account for the fact that so considerable an organ as the swimming bladder should have been denied to so many species, not only of the more indolent kinds, which dwell composedly at the bottom of the waters, but to many others which yield to none of their class in the ease and velocity of their movements. Its presence or absence does not even accord with the other conditions of organization; for while it is wanting in the common mackerel, it is found to occur in a closely allied species, the *Scomber pneumatophorus* of Laroche.

Another singular peculiarity connected with the organization of certain fishes may be also shortly noticed in this place, we mean the power of conveying electrical shocks. In Torpedos, the apparatus consists of membranous tubes filled with mucous matter, divided by transverse chambers closely set together, like the cells of honeycomb, and disposed in two groups placed on each side of the head. They receive enormous branches of nerves from the fifth and eighth pair. In the *Gymnotus* this extraordinary structure occupies the under surface of the body throughout its entire extent, and to a considerable thickness. It is composed of parallel plates separated by thin layers of mucilage. The effect of this natural galvanic pile will be detailed in the course of the systematic portion of this article, when we shall have occasion to mention the electric fishes in their proper place.

SECT. X.—THE GENERAL POSITION AND RELATIONS OF FISHES, CONSIDERED AS A GREAT CLASS IN THE ANIMAL KINGDOM.

It results not less from this general exposition of the structure of our present class, than from all observation of special organization, that fishes form a class of animals distinct from every other, and destined by the totality of their conformation to live, move, and have their being in the waters. The liquid element forms their proper place in the creation; there they had their origin, there they must remain till the final consummation of all things,—and it is either through slight and superficial approximations, or by vain metaphysical speculation, that any modern writer could regard them as proceeding from an exalted or more perfect development of the molluscous tribes. Equally unfounded is of course that other and corresponding opinion, which, in the spirit of the same philosophy, looks upon fishes as forming an elementary stage, or fœtal condition, of the other vertebrated classes. It is true that the Mollusca, in common with fishes, respire by means of branchiæ; they equally possess a nervous and circulating system, an intestinal canal and a liver; "and nobody," says Cuvier, with a justifiable pride, "knows these things better than I, who was the first to make known with any degree of completeness the anatomy and zoological relations of the molluscous tribes." As animal life, he continues,[3] has received but a limited number of organs, it necessarily happens that some of these organs are common to several classes. But where is in other respects the resemblance? The skeleton of these animals, and their entire system of locomotion, are they comparable in the least of their parts? And even such organs as are

[1] *De Aure et Auditu*, &c.

[2] In several insects of the genus *Blatta* we have observed a want of symmetry both in the size and markings of the elytra. We do not mean an accidental variation of one side, but an evidently pre-ordained disparity of form and colour.

[3] *Hist. Nat. des Poissons*, t. i. p. 544.

common alike to the Mollusca and to fishes, can they be brought into relation with those connections which the latter exhibit with the other vertebrated classes? By what passage does nature conduct us from the one to the other? It is certainly by no means difficult, while disregarding numerous disagreements, so to compose a definition as to embrace only those points which they possess in common; but that definition assuredly will always repose upon a pure abstraction of the mind, a definition simply nominal, an assemblage of vain words, which can never be represented by a harmonious and existing plan, notwithstanding whatever extraneous details may be collected or conceived in support of such visionary views. By a like procedure, there is in truth no two things, however remote or dissimilar, which may not be so allied; for, whatever their disresemblance, there will always be some particular point or other in which they may be found to agree. But when we look to the characters in which objects differ, we shall find reason to view the subject in another light. The heart itself in those Mollusca which have only one, is placed in a contrary mode from that of fishes; it is at the junction of the branchial veins and arteries of the body that that organ is attached; in several the members are placed upon the head, in others the generative system is lateral, and frequently the respiratory organs are placed above those of digestion, and extend more or less over the dorsal surface. Perhaps all that can be said regarding any positive or important relationship between Mollusca and fishes is, that both classes are possessed of branchiæ.

It may indeed be observed, that whenever we proceed from these purely verbal or metaphysical formula, we find ourselves lost among the most inadmissible comparisons. According to one theorist, the shells of bivalves represent the opercula of fishes; according to another, the buckler of the cuttle-fish is a true fibrous bone; according to a third, the large scales of the sturgeon, and the spines of the diodons, are to be regarded as an external skeleton. Others search for the desired analogies among the Crustacea, of which the margins of the thorax represent the opercula. Beneath these margins the branchiæ actually occur, but if we continue the comparison, all is changed. The medullary cord is towards the abdomen, the heart towards the back, and the latter organ, as among the Mollusca, receives the blood from the branchiæ, but does not send it thither. Finally, some observers, apparently despairing of their transcendental cause, perceive the rays or spiny apophyses of vertebrated animals in the legs of the Crustacea, forgetting that, were it so, an obvious degradation rather than amelioration of organic structure must have befallen the class of fishes.

The affinity of fishes to other classes of vertebrated animals is much better founded. At least we here find the commencement of sensible relations in the number of organic systems, and in their mutual connections; but we are still far from discovering a progressive and continuous course. We cannot in this place report the conclusive reasoning of Baron Cuvier regarding the distinctions of these classes. We shall merely state his conclusion to be, that if there is a resemblance between the organs of fishes and those of the other great groups of the animal kingdom, it is only in so far as the functions of such organs are similar; that if we assert either that fishes are Mollusca of an ameliorated or higher grade, or that they represent a commencing or fœtal state of reptiles, we can do so only in an abstract or metaphysical acceptation, and that even with that restriction we by no means convey an accurate notion of their organic structure; that we cannot regard them either as links of an imaginary chain of successive forms (of which none could serve as the germ of another, since none is capable of a solitary or isolated existence), nor of that other chain, not less fanciful, of simultaneous and transitionary forms, which has no reality but in the imagination of certain naturalists, more poetical than observant. They pertain in truth, and solely, to the actual chain of co-existent beings,—of beings necessary to each other, and which by their mutual action maintain the resplendent order and harmony of created things.

> These are thy glorious works, Parent of good,
> Almighty! Thine this universal frame,
> Thus wondrous fair; Thyself how wondrous then!
> Unspeakable, who sitt'st above these heavens,
> To us invisible, or dimly seen
> In these thy lowest works; yet these declare
> Thy goodness beyond thought, and power divine.

SECT. XI.—THE CLASSIFICATION OF FISHES.

The class of fishes is of all others the most difficult to divide into orders, according to fixed and perceptible characters. We shall here give a brief view of Baron Cuvier's arrangement, the details of which we shall afterwards exhibit in our systematic view.

Fishes are divisible, in the first place, into two great and distinct series, viz. FISHES PROPERLY SO CALLED, embracing the great majority of species; and CHONDROPTERYGIAN or CARTILAGINOUS FISHES, such as sharks and rays.

The general character of the latter series consists in the absence of the bones of the upper jaw, the place of which is supplied by those of the palate. Their entire structure also exhibits sundry analogies, to be afterwards described. Cartilaginous fishes are further divisible into three principal orders.

1*st.* CYCLOSTOMI, the jaws of which are soldered into an immoveable ring, and the branchiæ open by means of numerous holes. Example, the *Lamprey.*

2*d.* SELACHII, which possess the branchiæ of the Cyclostomi, but not their jaws. Example, *Sharks.*

3*d.* STURIONES, of which the branchial opening is in the usual fissure-like form, and furnished with an opercle. Example, *Sturgeons.*

The other great series, or that of the ORDINARY FISHES, presents a first subdivision into those in which the maxillary bone and the palatine arch are fixed to the cranium. They constitute Cuvier's order PLECTOGNATHI, which comprises two families, the GYMNODONTES and SCLERODERMI. Examples, the genera *Diodon* and *Ostracion.*

The next subdivision of the ordinary fishes contains certain species with perfect jaws, but the branchiæ of which, instead of being comb-shaped, resemble a series of small tufts. They constitute an order called LOPHOBRANCHII, which comprises the two genera SYNGNATHUS and PEGASUS of Linn. Example, the *Pipe-fish.*

Of the ordinary fishes there then remains an immense assemblage, to the general classification of which no other characters can be applied than those of the external organs of motion. After a long and laborious research, Baron Cuvier became satisfied that the least objectionable of these characters is still that long ago employed by Ray and Artedi, drawn from the nature of the first rays of the dorsal and anal fins. Thus the great body of the ordinary fishes is divided into MALACOPTERYGII, in which all the rays are soft, with the occasional exception of the first of the dorsal, or of the pectorals; and ACANTHOPTERYGII, in which the first portion of the dorsal, or the first dorsal if there are two fins of that kind, is always supported by spinous rays, and where some similar spines are also found in the anal fin, and at least one in each of the ventrals.

Of these two last-mentioned groups, the former, or

Malacopterygii, may be conveniently subdivided according to the position of the ventral fins, whether situate behind the abdomen, suspended to the apparatus of the shoulder, or entirely wanting. This view furnishes us with three great orders, the MALACOPTERYGII ABDOMINALES (such as pike, salmon, and herring), the M. SUBBRACHIATI (such as cod, haddock, and flat fish), and the M. APODES (such as eels).

But such a basis of subdivision is altogether inapplicable to the remaining group of ordinary fishes, viz. the ACANTHOPTERYGII, which at present can only be placed together in a certain series of natural families. Fortunately, several of these families are possessed of characters almost as precise as those which could be assigned to genuine orders. It is, however, impossible to assign to the families of fish the same marked gradation so perceptible among those of the Mammalia. Thus the Chondropterygians are related to serpents on the one hand by the organs of the senses, and in certain cases even by the generative system; while, on the other, they bear an alliance to the Mollusca and worms in the occasional imperfection of their skeleton.

Before proceeding with our systematic exposition of the minor divisions, we shall present our readers with a sketch of Baron Cuvier's views regarding the general character and relations of certain groups. After forty years devoted to the study of Ichthyology, that great observer became convinced that no acanthopterygian species ought to be mingled in classification with the fishes of other families, as attempted by many of his predecessors; and he also came to the conclusion that the acanthopterygian order, which comprises about three fourths of the entire class, contains the characteristic type, and is the most accordant and homogeneous, even amid all the variations which it undergoes.

The acanthopterygian character prevails over all the others, and these ought to be employed only as subservient to it, and never in opposition; but the extreme constancy of the general plan, and the predominating influence of the regulating character, render it a matter of greater difficulty to apply precise and perceptible characters of a subordinate nature. It is thus that the various families of the acanthopterygian order pass so insensibly from one to another, that we are often at a loss to define the transition. The family of Percidæ, for example, which is essentially distinguished from that of the Sciænidæ by its palatinal teeth, comprises a group of some extent, and extremely natural in its construction, which yet contains a portion of species possessed of those teeth, while the other portion is without them. The same thing happens in the family with mailed cheeks (joues cuirassées), the majority of which are allied to the perches,—the others to the Sciænidæ. The sciænoid genera themselves approach in part to the Chætodontes in the scales which in several instances more or less cover their vertical fins, and yet it is necessary to assimilate them still more closely to the Sparidæ, by reason, in many other instances, of the entire absence of those scales.

The malacopterygian families are distinguished by stronger and more obvious differences, and several of them are not only natural, but subjected to fixed limits, so that each, in its separation from the other, preserves within itself a great resemblance in details. This precision is so sensible, that the majority of natural families established by Cuvier in this part of the class had been already signalised by Artedi as generic groups. His *Siluri*, *Cyprini*, *Salmones*, *Clupeæ*, and *Esoces*, may remain unbroken, and there is even no inconvenience in distributing them according to the position of the ventral fins, because in those genera the character in question, however trivial in itself, is constant; but it is clearly impossible to preserve the distinction of jugular, thoracic, and abdominal fishes, in the mode established by Linnæus. It is, as Cuvier observes, of small consequence, in fact, whether the ventrals manifest themselves externally a little before or a little behind the pectorals, or immediately beneath them; but the circumstance of importance, as connected with the structure of the fish, is to ascertain whether the pelvis be attached to the bones of the shoulder, or whether it is simply suspended in the muscles of the abdomen. To designate the fish belonging to the former category, the name of *Sub-brachians* has been bestowed by Cuvier, and that without any reference to the external position of the ventrals,—that circumstance being dependent on the greater or less extent of the bones of the pelvis. To those of the second category he leaves the older name of *Abdominals.* Lastly, the term *Apodes* naturally designates the Malacopterygians destitute of ventral fins.

Cuvier's systematic exposition of fishes commences with the Acanthopterygians, which constitute in reality only a single family of vast extent. He then places in succession the various families of Malacopterygians, in the order in which they seem allied to the preceding great division; but he guards the student from inferring that these relations follow only in a single line or series. If the abdominal Malacopterygians may be so arranged, and may even be made to commence with those which possess some spiny rays, they are not followed in so natural a succession by either the apodal or sub-brachian tribes. The *Gadi*, for example, are as nearly related as any of the Abdominals to certain species of the acanthopterygian order, and there would be no reason for placing them after the Abdominals if the question were mooted respecting the station they should hold in nature. If they are actually arranged subsequent to the latter in our systems, it is because the exposition of facts in a book necessarily requires a successive order.

The spirit of the same observation is applicable to the rest of the fishes;—to those of which the upper jaw is fixed (*Plectognathi*),—to such as have tufted branchiæ (*Lophobranchii*),—and, above all, to the great and important series of Chondropterygians, which terminate the class. It is indeed chiefly among those last mentioned that we perceive the futility of whatever system seeks to arrange the objects of creation in a single line. Several of the genera alluded to, the rays and sharks, for example, may be said to rise above the rank of ordinary fishes by the complicated nature of some of their organs of sense, and by that of the generative system, which is more fully developed in some particulars than even that of birds;—while other genera of the same series, and at which we arrive by graduated transitions, such as the Lampreys and Ammocætes, become so simplified in their structure, that they have even been regarded as affording a connecting link between the class of fishes and that of the articulated worms. The genus *Ammocœtes* certainly possesses no skeleton, and its muscular apparatus is attached solely to tendinous or membranous supports.

Let it not therefore be imagined, says Cuvier, that because one genus or family is placed anterior to another, it is for that reason to be regarded as more perfect, or superior to those that follow. He alone will indulge in that fond fancy, who pursues the chimerical project of ranging beings in a single series,—a project, be it remembered, now renounced by philosophy. The further we advance into the penetralia of the temple of nature, the more we shall feel convinced that a falser notion was never entertained in relation to natural history. Genuine systems view each being not as intermediate merely to two others, but as central among many;—they show the wonderful radiations that link it more or less immediately with the vast web of organic life; and it is by such extended views alone that

Introduction.

we shall acquire ideas worthy of nature and of nature's God. It is therefore not so much in the position which a being occupies in our published systems, which are necessarily linear or consecutive, that we are to seek for those multifarious relations, or for the actual degree of organisation,—but in accurate descriptions of structure afforded by those who possess the use of their eyes and pen. It is not, however, to be in any way maintained that no direct classification is possible, or that species should not be formed into groups, and embraced by definitions. These approximations are on the contrary so real, that the natural understanding of man has ever inclined towards them, and in all ages and countries the vulgar as well as the learned have formed their genera. It is in truth one of the great objects of science to render the various groups into which, for our own convenience, we must arrange the objects of creation, as natural in themselves, and as nearly related to their neighbours, as is consistent with the necessity of placing them in our descriptive systems in a single fixed position,—a position, be it remembered, in which their numerous and mixed relations can neither be philosophically exhibited nor fully expressed.

We here terminate our introductory chapter, or general exposition of the class of fishes, and shall now proceed to a detailed enumeration of the characters of the principal genera, adding, as occasion requires, a succinct description and history of the most interesting or important species. We give in a note below a tabular abstract of the Ichthyological System.[1]

---

[1] *Systematic View of the Orders, Families, Genera, and Sub-genera of Fishes, according to the arrangement of Baron Cuvier.*

N. B.—In this abstract we follow the system of the *Règne Animal*, as sufficing for a tabular view ; but in the body of our article we shall introduce notices of such new or amended genera as have been signalised by our illustrious guide in those volumes of the *Hist. Nat. des Poissons*, which have made their appearance posterior to the publication of the second edition of the *Animal Kingdom*.

CLASS FISHES.

First Great Series, called ORDINARY or OSSEOUS FISHES.

ORDER I.—ACANTHOPTERYGII.

FAMILY I.—PERCIDÆ.

With thoracic ventrals.

Seven branchial rays, two dorsals, teeth small and crowded.

Perca.
Labrax.
Lates.
Centropomus.
Grammistes.
Aspro.
  Huro.
  Etelis.
  Niphon.
  Enoplosus.
  Diploprion.
Apogon.
  Cheilodipterus.
  Pomatomus.

Some of the teeth long and pointed.

Ambassis.
Lucio-Perca.

With a single dorsal, and canine teeth.

Serranus.
  Serranus proper.
  Anthias.
  Merrus.
Plectropoma.
Diacope.
Mesoprion.

With a single dorsal, and small crowded teeth.

Acerina.
Rypticus.
Polyprion.
Centropristis.
Gristes.

With less than seven branchial rays.

A single dorsal, and some canine teeth.

Cirrhites.

A single dorsal, all the teeth small and crowded.

Chironemus.
Pomotis.
Centrarchus.
Priacanthus.
Dules.
Therapon.
  Datnia.
Pelates.
Helotes.

Two dorsals.

Trichodon.
Sillago.

With more than seven branchial rays.

Holocentrum.
Myripristis.
Beryx.
Trachicthys.

With jugular ventrals.

Trachinus.
Percis.
Pinguipes.
Percophis.
Uranoscopus.

With abdominal ventrals.

Polynemus.
Sphyræna.
Paralepis.
Mullus.
  Mullus proper.
  Upeneus.

FAMILY II.—BUCCÆ LORICATÆ, OR MAILED CHEEKS.

Trigla.
  Trigla proper.
  Prionotus.
  Peristedion.
  Dactylopterus.
Cephalacanthus.
Cottus.
  Cottus proper.
  Aspidophorus.
Hemitripterus.
Hemilepidotus.
Platycephalus.
Scorpæna.
  Scorpæna proper.
  Tænianotes.
  Sebastes.
Pterois.
Blepsias.
Apistus.
Agriopus.
Pelor.
Synanceia.
Menocentris.
Gasterosteus.
Oreosoma.

FAMILY III.—SCIÆNIDÆ.

With two dorsals.

Sciæna.
  Sciæna proper.
  Otolithus.
  Ancylodon.
  Corvina.
  Johnius.
  Umbrina.
  Pogonias.
Eques.

With one dorsal, and seven branchial rays.

Hæmulon.
Pristipoma.
Diagramma.

With less than seven branchial rays, the lateral line continuous.

Lobotes.
Cheilodactylus.
Scolopsides.
Micropterus.

With less than seven branchial rays, the lateral line interrupted.

Amphiprion.
Premnas.
Pomacentrus.
Dascyllus.
Glyphisodon.
Heliasus.

FAMILY IV.—SPARIDÆ.

Sparus.
Sargus.
Chrysophris.
Pagrus.
Pagellus.
Dentex.
  Pentapoda.
  Lethrinus.
Cantharus.
Boops.
Oblada.

FAMILY V.—MENIDÆ.

Mæna.
Smaris.
Cæsio.
Gerres.

FAMILY VI.—SQUAMMIPENNES.

Chætodon.
  Chætodon proper.
  Chelmon.
  Heniochus.
  Ephippus.
    Taurichtes.
  Holocanthus.
    Pomocanthus.
  Platax.
Psettus.
Pimelepterus.
Dipterodon.
Brama.
Pempheris.
Toxotes.

FAMILY VII.—SCOMBERIDÆ.

Scomber.
  Scomber proper.
  Thynnus.
  Orcynus.
  Auxis.
  Sarda.
  Cybium.
  Thyrsites.
  Gempylus.
Xiphias.
  Xiphias proper.
  Tetrapturus.
  Makaira.
  Histiophorus.
Centronotus.
  Naucrates.
  Elacates.
  Lichia.
  Trachinotus.

FIRST GREAT SERIES OF THE CLASS OF FISHES.

ORDINARY OR OSSEOUS FISHES.

ORDER I.—ACANTHOPTERYGII.

These, as already mentioned, form much the most numerous division of the class. They are distinguished by the spines, which occupy the place of the first rays of the dorsal fin, or which alone sustain the anterior dorsal when there are two. Sometimes, instead of an anterior dorsal, there are only a few free spines. The first rays of their anal fin are also spinous, and there is generally one of a similar nature to each of the ventrals. The Acanthopterygians bear so many relations to each other,—their several natural families exhibit so many variations in the apparent characters which one might suppose capable of indicating orders or other subdivisions,—that it has been found impossible to divide them, otherwise than by those natural families themselves, which are thus left without any higher combinations.

FAMILY I.—PERCIDÆ.

So named because well typified by the common perch. Their bodies are of an oblong form, covered with scales, which are generally hard and rough; the opercle and preopercle, and frequently both, have the margins toothed or

---

Rhinchobdella.
Macrognathus.
Mastacembelus.
Notocanthus.
Seriola.
Nomeus.
Temnodon.
Caranx.
Caranga.
Citula.
Vomer.
Olistus.
Scyris.
Blepharis.
Gallus.
Argyreiosus.
Vomer proper.
Zeus.
Zeus proper.
Capros.
Lampris.
Equula.
Mene.
Stromateus.
Pampla.
Peprilus.
Luvarus.
Seserinus.
Kurtus.
Coryphæna.
Coryphæna proper.
Caranxomorus.
Centrolophus.
Astrodermus.
Pteraclis.

FAMILY VIII.—TÆNIOIDÆ.

The muzzle elongated, teeth strong.

Lepidopus.
Trichiurus.

The muzzle short, mouth small.

Gymnetrus.
Stylephorus.

The muzzle short, mouth cleft, head obtuse.

Cepola.
Lophotes.

FAMILY IX.—THEUTIDÆ.

Siganus.
Acanthurus.
Prionurus.
Naseus.
Axinurus.
Priodon.

FAMILY X.—LABYRINTHIFORM PHARYNGEALS.

Anabas.
Polyacanthus.
Macropodius.
Helostoma.
Osphromenus.
Trichopodus.
Spirobranchus.
Ophicephalus.

FAMILY XI.—MUGILIDÆ.

Mugil.
Tetragonurus.
Atherina.

FAMILY XII.—GOBIDÆ.

Blennius.
Blennius proper.
Pholis.
Myxodes.
Salarias.
Clinus.
Cirrhibarba.
Gunellus.
Opistognathus.
Zoarcus.
Anarrhicas.
Gobius.
Gobius proper.
Gobioides.
Tænioides.
Periopthalmus.
Eliotris.
Callionymus.
Trichonotus.
Comephorus.
Platypterus.
Chirus.

FAMILY XIII.—PECTORALES PEDICULATI.

Lophius.
Lophius proper.
Chironectes.
Malthe.
Batrachus.

FAMILY XIV.—LABRIDÆ.

Labrus.
Labrus proper.
Cheilinus.
Lachnolaimus.
Julis.
Anampses.
Crenilabrus.
Coricus.
Epibulus.
Clepticus.
Gomphosus.
Xirichthys.
Chromis.
Cychla.
Plesiops.
Malacanthus.
Scarus.
Calliodon.
Odax.

FAMILY XV.—FISTULARIDÆ.

Fistularia.
Fistularia proper.
Aulostomus.
Centriscus.
Centriscus proper.
Amphisile.

ORDER II.—MALACOPTERYGII ABDOMINALES.

FAMILY I.—CYPRINIDÆ.

Cyprinus.
Cyprinus proper.
Barbus.
Gobio.
Tinca.
Cirrhinus.
Abramis.
Labeo.
Catastomus.
Leuciscus.
Chela.
Gonorhynchus.
Cobitis.
Anableps.
Pæcilia.
Lebias.
Fundulus.
Molinesia.
Cyprinodon.

FAMILY II.—ESOCIDÆ.

Esox.
Esox proper.
Galaxias.
Alepocephalus.
Microstoma.
Stomias.
Chauliodus.
Salanx.
Belone.
Scomberesox.
Hemiramphus.
Exocetus.
Mormyrus.

FAMILY III.—SILURIDÆ.

Silurus.
Silurus proper.
Schilbe.
Mystus.
Pimelodes.
Bagrus.
Pimelodes proper.
Synodontis.
Ageneiosus.
Doras.
Heterobranchus.
Macropteronotes.
Plotosus.
Callichthys.
Malapterurus.
Platystachus.
Loricaria.
Hypostomus.
Loricaria proper.

FAMILY IV.—SALMONIDÆ.

Salmo.
Salmo proper.
Osmerus.
Mallotus.
Thymallus.
Coregonus.
Argentina.
Characinus.
Curimata.
Anostomus.

spiny; and the jaws, the front of the vomer, and almost always the palatine bones, are furnished with teeth.

The species of this family are extremely numerous, especially in the tropical seas. Their flesh is in general wholesome, and of an agreeable flavour. By far the greater number have their ventral fins attached beneath the pectoral, and thus form a first division, named

THORACIC PERCIDÆ.[1]

A. *Seven branchial rays; two dorsal fins.*

a. *All the teeth small and crowded.*

GENUS PERCA, Cuv. Pre-opercle dentated; bony opercle terminated by two or three sharp points; tongue smooth. Sometimes the sub-orbital and humeral bones are slightly dentated.

The common perch (*Perca fluviatilis*, Linn.), Plate CCXCVIII. fig. 1, one of the most beautiful of the fresh-water fishes of Europe, is too familiarly known to require description. It inhabits both lakes and rivers, but shuns salt water.[2] As an article of food it is still in some estimation, although the character given of it in that respect by Ausonius is higher than accords with modern views. The female deposits her ova, united together by a viscid matter, in lengthened strings, a peculiarity noted by Aristotle. The number of these eggs sometimes amounts to nearly a million. The perch occurs over all Europe, and most of the northern districts of Asia. Pennant alludes to one said to have been taken in the Serpentine River, in Hyde Park, which weighed nine pounds. But even one half of that weight would be regarded as extraordinary in the present species.

The *Perca Italica* occurs in the south of Europe, and is distinguished by the want of the black bands so conspicuous in the common kind. Several other species are found in North America. *P. ciliata* is a native of Java; and *P. trutta* occurs in Cook's Strait, New Zealand.

GENUS LABRAX, Cuv. Distinguished from the preceding by scaly opercula terminating in two spines, and by the roughness of the tongue.

To this genus belongs the basse or sea-perch (*P. labrax*, Linn.; *Labrax lupus*, Cuv.), Plate CCXCVIII. fig. 2, a fish of a chaste and pleasing aspect, though destitute of the more strongly contrasted colours of the fresh-water species. Its upper parts are gray, with bluish reflections, which gradually shade away into a silvery whiteness on the under surface. The pectoral fins are slightly tinged with red. It occurs along the Dutch and British shores, but is

- Gastrobranchus.

Ammocætes.

[1] Almost all the species were included by Linnæus in his genus PERCA, but Cuvier has divided them, as shown above, according to the amount of the rays of the branchiæ, the number of the dorsal fins, and the nature of the teeth.

[2] Pallas, however, is said to have remarked, in a work, we believe, still unpublished (*Zoographia Russo-Asiatica*), that about spawning time both pike and perch are found in a gulf of the Caspian Sea, about thirty verstes from the mouth of the Terek.

much more abundant in the Mediterranean. It is a voracious fish, remarkable for the size of its stomach, and was known to the ancients under the appropriate name of *lupus*.

GENUS LATES, Cuv. Scarcely differs from Perca, except in having deep dentations, and even a small spine at the angle of the pre-opercle, and by stronger dentations also on the sub-orbital and humeral bones.

We shall here notice only the *L. Niloticus*, the largest and one of the finest-flavoured fishes of the celebrated Nile. It is altogether of a silvery tint, tinged on the upper parts and fins with olive brown. Individuals of a very great size are sometimes found in Upper Egypt, and, according to Paul Lucas, the species occasionally attains to the weight of 300 pounds. Other kinds occur in India, where they are highly esteemed as food.

GENUS CENTROPOMUS, Lacépède. Pre-opercle dentated; opercle obtuse, and unarmed.

C. *undecimalis*, Cuv. is a large and excellent fish, known along a great extent of the South American shores, where it is much used as an article of consumption, under the name of *brochet* or pike. In the form of its muzzle, and general shape, it somewhat resembles that fresh-water fish, and indeed it frequently ascends the great rivers to a considerable height. A kind of caviar is made of its row. It attains to the weight of twenty-five pounds.

GENUS GRAMMISTES, Cuv. Opercle and pre-opercle spined, but not dentated; dorsal fins approximate; scales small, as if sunk beneath the epidermis; anal fin without apparent spine.

Of this genus there seems to be only a single species, *G. orientalis*, a small fish, native to the Indian seas.

GENUS ASPRO, Cuv. Body elongated; dorsals not approximate; ventrals broad; teeth small and close (en velours); head depressed; muzzle reaching beyond the mouth, and terminating in a rounded point.

We are acquainted with only two species of this genus, both of which are known in the fresh waters of the continent of Europe. We have represented *A. vulgaris* (*Perca asper*, Linn.), on Plate CCXCVIII. fig. 3. It is a small fish, rarely exceeding half a foot in length, common in the Rhone, especially between Lyons and Vienne.

We shall here pass over some limited genera, of which the species are all foreign to Europe; such as HURO, which contains the black bass, or black perch, of the English inhabitants of the banks of the Huron; ETELIS, NIPHON, ENOPLOSUS, and DIPLOPRION. The species of the last two genera are remarkable as resembling Chætodons in their general form, rather than percoid fishes.

GENUS APOGON, Lacépède. Body short, and, in common with the opercles, furnished with large scales which are easily dislodged; dorsal fins very separate; a double dentated border on the pre-opercle.

The *Apogon rex Mullorum* of Cuvier (*Mullus imberbis*, Linn.) is a small Mediterranean species, of a red colour, with a black spot on each side of the tail. It measures about three inches in length. The foreign species seem chiefly confined to the Indian seas, at least they have not yet been observed in those of Africa or America. A few have been met with along the shores of New Holland, New Guinea, &c.

GENUS POMATOMUS, Risso. Resembles the preceding in the separation of its dorsals, and its deciduous scales; but the pre-opercle is simply striated, the opercle emarginate, and the eye enormously large.

The only known species is the *P. telescopium*, a fish of excessive rarity. According to Risso, it scarcely ever leaves the bottom of the deep sea. He is aware of only two specimens having been taken near Nice during a period of thirty years. It measures about twenty inches in length. The colours are brownish violet, with red and blue reflections, the fins being brownish black. Whether the prodigious dimensions of its eyes are in any way connected with the depth and consequent darkness of its abode, is a point which we have not at present any means to determine.

b. *Some long and pointed teeth mixed with the close-set kind.*

GENUS AMBASSIS, Commerson. Resembles Apogon in form; the pre-opercle has a double dentation towards the base, and the opercle terminates in a point; but the two dorsals are contiguous, and the anterior one is preceded by a spine.

A peculiarity in the intestinal canal, that is, the want of appendages to the pylorus, renders the present position of this genus in the system somewhat doubtful. The species are small fishes found in the fresh waters of India. One of them, *A. Commersonii*, Cuv. is abundant in a small lake in the island of Bourbon, where it is prepared as the Europeans do anchovies.

GENUS LUCIO-PERCA, Cuv. Margin of the pre-opercle with only a simple dentation, dorsal fins not approximate.

This genus receives its name from the supposed combination which certain of its species exhibit of the characters of the pike and perch,—that is, they possess the fins and banded markings of the latter, with the elongated head and body, and acute lengthened teeth, of the former. The best known species is the *L. sandra* of Cuvier (*Perca lucioperca* of Bloch), an excellent fish, found in the lakes and rivers of Germany and the east of Europe, but unknown in France, Italy, and England. It sometimes attains to the size of a large salmon. Its growth is remarkably rapid, and its flesh is said to be rich and agreeable. Great quantities, preserved by salt or smoke, are exported from Prussia and Silesia.

B. *Seven branchial rays; only one dorsal fin.*

This subdivision is divisible, like the preceding, according to the nature of the teeth, the spines and dentations of the opercles, and other characters.

a. *Teeth hooked or canine.*

GENUS SERRANUS, Cuv. Pre-opercle dentated, bony opercle terminated by one or more points.

This extensive genus has been recently partitioned into several minor groups. SERRANUS proper contains the *Perca scriba* of Linn.; so called on account of some peculiar markings in the cheeks, resembling written characters.[1] ANTHIUS is represented by *A. sacer* of Bloch, a beautiful fish of the Mediterranean, of a ruby-red colour, changing into gold and silver, with yellow bands upon the cheeks. The third ray of the dorsal fin is greatly elevated, and the ventrals are much prolonged. This fish appears to have been known to ancient writers, and was regarded as sacred by the divers for marine productions, from the fond belief that no dangerous species would approach its haunts. When an individual happen-

[1] The smooth Serranus (*S. cabrilla*, Cuv.; *Perca channus*, Couch) has been described as a British species. Mr Couch regards it as a common fish, well known to the Cornish fishermen. He mentions (*Magazine of Nat. Hist.* vol. v. p. 19) that it keeps in the neighbourhood of rocks not far from land; and adds, as a singular fact, that the spasm which seizes it when taken never passes off. Hence it is found long after death in a state of rigidity and contortion, with the fins preternaturally erect. Both Cuvier and Cavolini have described this and other species of the genus as actual hermaphrodites,—one portion of each lobe of roe consisting of true ova, the other having every appearance of a perfect milt.

ed unfortunately to be caught by the fisherman's hook, it was supposed that its companions immediately severed the line by means of their sharp spines. Merrus of Cuv. contains the *Perca gigas* of Gmelin, a species which sometimes attains to the weight of sixty pounds.[1] This subdivision of the genus Serranus contains a great amount of species. The only other which we shall here mention is that which we have shown in Plate CCXCVIII. fig. 4, under the name of *Serranus altivelis*, which is chiefly remarkable for the great size of the posterior portion of the dorsal fin. It occurs in the seas around Java.

Genus Plectropoma, Cuv. Differs from Serranus chiefly in the more or less numerous dentations of the inferior margin of the pre-opercle, being directed obliquely forward,—recalling in some measure the teeth of the rowel of a spur. All the species are foreign to Europe; and the same observation applies to the genus Diacope, the characters of which we shall not here detail.

Genus Mesoprion, Cuv. Agrees with Serranus in its teeth, fins, and dentated pre-opercle, but differs in its opercle being terminated by an obtuse angle, not spinous. The species are remarkable for the varied richness and lustre of their colours. They inhabit both the eastern and western seas, but occur chiefly in those of India, China, and Japan, concealing themselves in the hollows of rocks, and leaving their sombre haunts only during fine weather, to prey on the delicate Mollusca with which those waters swarm. Many of the species are large, and excellent as articles of food. *M. vivanus* attains the weight of forty pounds. We have figured, on Plate CCXCVIII. fig. 5, an American species of great beauty, described by Cuvier under the name of *M. uninotatus*. The back and upper portion of the head and cheeks are of rich steel blue, the lower part of the cheeks and sides of a fine rose colour, the abdomen silvery. The entire body is coursed by many bands of a golden hue, irregular and disconnected on the dorsal surface. The dorsal fin is rose-colour, with three yellow bands; the other fins are gamboge yellow. This species seldom much exceeds a foot in length.

b. *Teeth fine, and closely set.*

Genus Acerina, Cuv. Distinguished by cavities or depressions in the bones of the head, and by the opercle and pre-opercle having only small spines, without dentations.

We shall here name only the *Acerina vulgaris* (*Perca cernua*, Linn.), a British species, commonly called the ruffe, much esteemed for the delicacy of its flesh. Mr Yarrell informs us that it is common to almost all the canals and rivers of England, particularly the Thames, the Isis, and the Cam. Though said to be unknown in Spain, Italy, and Greece, it occurs pretty generally over the colder portion of the European continent, preferring slow, shaded streams, and a gravelly bottom.[2]

It is angled for with a small red worm, and being gregarious, six or eight dozen may sometimes be taken at a single stand.

Genus Rypticus, Cuv. Small spines on the opercles; scales likewise small, and concealed, like those of Grammistes, beneath a thick epidermis. The genus, however, is well distinguished from the latter by the single dorsal fin. The species have been named *Savonniers* by the French, in consequence of their soft and soapy surface, which feels as if it had been lubricated by some unctuous matter.

Genus Polyprion, Cuv. In addition to spines on the opercle, and dentations on the pre-opercle, the former is furnished with a rough bifurcated crest, and the bones of the head generally are marked by asperities.

P. *cernium* is an enormous fish, extremely common in the Mediterranean, but very indistinctly characterised or understood before the time of Cuvier and his able coadjutor M. Valenciennes. It attains the length of five or six feet, and sometimes weighs a hundred pounds. The flesh is white, tender, and well tasted. It is frequent, according to Risso, near Nice, where it delights in rocky bottoms, and is occasionally captured at the vast depth of three thousand feet.

Cuvier here places the singular genus Pentaceros, of which the sole species, bearing some resemblance in its general aspect to the *Ostracion auritus* of Shaw, was brought to Holland by M. Horstock. We shall here likewise merely name the genera Centropristis and Gristes of Cuvier, the former containing the *Black Harry* of the Americans, an excellent fish, common near New York,—the latter, the species called *growler* in the United States.

The ancient unrestricted genus Perca, as defined by Artedi and Linnæus, terminates in this place. But there remains a large assemblage of allied species referrible to various distinct genera, though still pertaining to the great family of Percidæ.

C. *With less than seven branchial rays.*

a. *With a single dorsal fin, and canine teeth mingled with the others.*

In this subdivision we place the genus Cirrhites alone. The species are from the Indian seas, and have only six branchial rays.

b. *With a single dorsal fin, and small close-set teeth.*

Here are classed the genera Chironemus, Centrarchus, and Pomotis. To the last belongs the *P. vulgaris*, Cuv. (*Labrus auritus*, Linn.), called pond-perch in New York. It is frequent in mill-dams and other tranquil waters, and is often angled for in America, both for pleasure and profit. According to Dr Richardson, it is called *sun-fish* around Lake Huron. See Plate CCXCVIII. fig. 6. Of the genus Priacanthus we shall merely observe, that the species are peculiar to the seas of hot climates. The genus Dules resembles *Centropristis* already described, except that it possesses only seven branchial rays. *D. rupestris* bears resemblance to a carp, and is found in the fresh waters of the islands of Bourbon and the Mauritius, where it is highly esteemed for the excellence of its flavour. We have figured one of the most remarkable of the genus (Plate CCXCVIII. fig. 7), named *Dules auriga* by Cuvier, on account of the long whip-like form assumed by the third spine of the dorsal fin. It was brought from Brazil by M. Delalande.

We shall conclude this subdivision by a brief notice of the genera Therapon, Datnia, Pelates, and Helotes. It has been observed that these constitute a group, formed, as it were, to make naturalists despair, by showing how nature laughs at what we deem characteristic combinations. The genera above named, possessing a multitude of mutual relations, as well interior as external, sufficient to forbid their distant separation, and bearing a great resemblance to the entire percoid family, at the same time combine species furnished with palatine teeth,

---

[1] It is synonymous with *Perca robusta* of Mr Couch, made known by that gentleman as a British species, from a single specimen taken with a line. (See *Magazine of Natural History*, vol. v. p. 21.)

[2] *History of British Fishes*, p. 18.

along with other species which seem to be constantly deprived of these organs. They also possess close-set teeth in the jaws, and dentations on the sub-orbital, the pre-opercle, and not unfrequently on the shoulder bone; none has more than six branchial rays; no scales are visible on the cranium, muzzle, or maxillæ; the dorsal spines are folded back into a groove of the back; and the swimming bladder is constantly divided by a restriction into two distinct sacks, as in *Cyprinus*, *Choracinus*, and *Myripristis*,—a character somewhat remarkable in any group of the acanthopterygian order.

c. *With two dorsal fins.*[1]

Genus Trichodon, Steller. Pre-opercle with several strong spines; opercle terminating in a flattened point; no scales; mouth almost vertically cleft.

Of this genus only one species has been yet discovered, the *T. Stelleri* of Cuv. It was found by the unfortunate Steller near Cape Cronock, and especially at the island of Unalaschka. It inhabits sandy shores, in which it conceals itself on the ebbing of the tide, and is there collected by the natives with their hands. The females deposit their eggs in little hollows in the sand, and offer, it is said, an exception to the ordinary instinct of fishes, in attending to their young ones after they are hatched.

Genus Sillago, Cuv. Head somewhat drawn to a point; mouth small; small crowded teeth on the jaws, and before the vomer; opercle terminating in a small spine; six branchial rays; dorsal fins contiguous;—the spines of the first slender, of the second long and low.

The species occur in the Indian Seas, and are held in high esteem for the delicate flavour and brightness of their flesh. The most noted species is the *peche madame* of Pondicherry (*S. domina*), of a brownish colour, and remarkable for the first ray of the dorsal fin being elongated to a filament as long as the body. Another species, called *Soring* by Russell (the *Sciæna malabarica* of Bloch), measures about a foot in length, and is of a fulvous colour. It is regarded as one of the best fishes in India.

D. *With more than seven branchial rays.*

The genera of this group, besides possessing eight branchial rays, are distinguished by this further peculiarity, otherwise unexampled among the acanthopterygian tribes, that they possess, besides the spine, seven soft rays, or even more, to each of the ventral fins. Many of the species are remarkable for their beauty.

Genus Holocentrum, Artedi. Scales brilliant and dentated; opercle dentated and spinous; pre-opercle not only dentated, but furnished at its angle with a strong spine directed backwards.

The species of this genus are widely distributed, occurring in the warmer portions of both the Pacific and Atlantic Oceans. Few species are more remarkable, either for the magnificence of their integuments, or the strength of their spines. The lustre of their scales equals that of a mirror, and is rendered still more brilliant by bands of red and spots of brown variously distributed. They bear a close resemblance to each other. That which we have selected as an illustration (Plate CCXCVIII. fig. 8) is the *H. hastatum* of Cuvier, which exists in the Royal Museum of Paris. Its native country is unknown, although it is presumed to have been brought from the African coast, and seems identical with specimens more recently collected by MM. Quoy and Gaymard at the Cape de Verd Islands.

Genus Myripristis, Cuv. Resembles the preceding in splendour, form, and scales; but the pre-opercle has a double dentated margin, and wants the spine at the angle.

This genus is remarkable for its swimming bladder being divided into two portions, of which the anterior is bilobed and attached to the cranium in two places, where it is merely covered by a membrane, and which correspond to the cavities of the ears.

The genera Beryx and Trachichtys are nearly allied to the preceding. The latter was originally characterised, and somewhat vaguely, by Dr Shaw, from a specimen received from the New Holland seas.

All the percoid fishes to which we have hitherto alluded are characterised by having their ventral fins inserted beneath the pectorals. But in several genera these important organs are otherwise placed. Thus, in the ensuing group, their position is in advance of the pectorals, that is, upon the throat. They are hence called

Jugular Percidæ.

Genus Trachinus, Linn. Head compressed; eyes approximate; mouth oblique; first dorsal very short, the second very long; pectorals large; opercle furnished with a strong spine.

Several of the species occur in the European seas, and two species, known in our own country as the greater and lesser weevers (*T. major* and *draco*), occur occasionally on the English coasts. They remain concealed in the sand, and the wounds inflicted by their spines are not only painful, but dangerous.

"That the greater weever," observes Mr Yarrell, "prefers deep water, that it lives constantly near the bottom, that it is tenacious of life when caught, and that its flesh is excellent, are four points that have been already noticed; but this subject, in reference to fishes generally, may be farther illustrated. It may be considered as a law, that those fish that swim near the surface of the water have a high standard of respiration, a low degree of muscular irritability, great necessity for oxygen, die soon, almost immediately, when taken out of water, and have flesh prone to rapid decomposition. On the contrary, those fish that live near the bottom of the water have a low standard of respiration, a high degree of muscular irritability, and less necessity for oxygen; they sustain life long after they are taken out of the water, and their flesh remains good for several days. The carp, the tench, the various flat fish, and the eel, are seen gaping and writhing on the stalls of the fishmongers for hours in succession; but no one sees any symptom of motion in the mackerel, the salmon, the trout, or the herring, unless present at the capture. These four last named, and many others of the same habits, to be eaten in the greatest perfection, should be prepared for table the same day they are caught;[2] but the turbot, delicate as it is, may be kept till the second day with advantage, and even longer without injury; and fishmongers generally are well aware of the circumstance, that fish from deep water have the muscle more dense in structure,—in their language, more firm to the touch,—that they are

[1] In the indication of this group in the *Règne Animal*, t. ii. p. 149, there seems to be a typographical error where the words "à moins des *six* rayons branchiaux" are used, instead of *sept*. The mistake has been copied as a matter of course into all the English and American translations.

[2] The chub swims near the top of the water, and is caught with a fly, a moth, or a grasshopper, upon the surface; and Isaac Walton says, "But take this rule with you—that a chub newly taken and newly dressed is so much better than a chub of a day's keeping after he is dead, that I can compare him to nothing so fitly as to cherries newly gathered from a tree, and others that have been bruised and lain a day or two in water."

of finer flavour, and will keep longer, than fish drawn from shallow water.

"The law referred to has its origin in the principles of organization; and though it would be difficult for the anatomist to demonstrate those deviations in structure between the trout and the tench which give rise to these distinctions and their effects, it is only necessary to make the point of comparison wider to be assured of the fact.

"Between a fish with a true bony skeleton, the highest in organization among fishes, and the lamprey, the lowest, the differences are most obvious. If we for a moment consider the lamprey, which is the lowest in organization of the vertebrated animals, with only a rudimentary vertebral column, as the supposed centre of zoological structure, and look from thence up and down the scale of organization, we on the extreme on one side arrive at man, to whom division of his substance would be destruction; but on the other we come to the polype, the division of which gives rise to new animals, each possessing attributes, not only equal to each other, but equal also to the animal of which they previously formed but a small part."[1] The species represented in our accompanying illustration (see Plate CCXCVIII. fig. 9) is *T. radiatus*, well known in the Mediterranean.

The Trachini of exotic regions, if such exist, are unknown. They are in some measure represented there by the genus Percis of Bloch and Schneider, which is found in the Indian, African, and New Holland seas.

The genus Pinguipes, of a heavy form, is distinguished by its strong conical teeth; its fleshy lips, and teeth upon the palate; and by its thick ventrals. The only known species is from Brazil. The genus Percophis, on the contrary, is much elongated in its shape (combining, as it were, that of the perch and serpent,—from whence the name); some of the teeth are long and pointed, and the extremity of the lower jaw projects. The sole species is a rare and remarkable fish from Rio Janeiro, discovered by the French naturalists attached to Freycinet's expedition.

Genus Uranoscopus, Linn. Eyes placed on the upper surface of a nearly cubical-shaped head; mouth vertically cleft; pre-opercle crenate towards its base; a strong spine at each shoulder; gills with only six rays.

In the interior of the mouth of this remarkable genus, and in front of the tongue, there is a long and narrow shred, which they can exsert at pleasure, and which it is said they use while lying concealed in the mud, to attract their prey, consisting of the smaller fishes. Another singularity in their structure consists in the immense size of the gall-bladder, a fact well known to ancient observers. In some of the species the first dorsal, which is small and spinous, is separated from the second, which is soft and long. Such is *U. scaber*, a Mediterranean species, not unfrequently used as food, although of a most ugly and repelling aspect. In others the dorsal is single, and its spinous and softer parts continuous. Such is *U. inermis*, the species represented in Plate CCXCVIII. fig. 10, which attains to the length of a couple of feet, and is native to the coast of Coromandel. It dwells in the sand, and the Indian fishers allege, what is no doubt a gross exaggeration, that it sometimes penetrates to a depth of twenty feet.

In the third principal division of the percoid family the ventral fins are inserted behind the pectorals. They are hence named

Abdominal Percidæ.

Genus Polynemus, Linn. Several of the inferior rays of the pectorals free, and forming so many filaments; ventrals not greatly posterior to the pectorals; pelvis still suspended to the bones of the shoulder.

The species are allied to the Percidæ in general by the close set teeth upon their jaws, vomer, and palate; but they possess the arched or convex snout, and the scaly vertical fins, which distinguish so many of the Sciænidæ. Their two dorsals are distant; their pre-opercle dentated, and their mouths greatly cleft. They appear to inhabit the seas of all warm countries. *P. longifilis* of Cuv. (*P. paradiseus* and *quinquinarius*, Linn.) is the noted *mango-fish* of India, so called from its fine yellow colour. According to Russel and Hamilton Buchanan, it is the most delicious of all the species eaten in Bengal. It is fished for all the year round, at the mouths of rivers, where the waters are saline. It ascends to some distance about spawning time in spring, but not beyond the influence of the tide. When in prime condition, the mango-fish, though only a few inches long, sells so high as a rupee. The eggs are also much esteemed. The colours of this species, like those of other fishes, seem to vary greatly, probably in relation to the condition of individuals, or the season of the year. M. Dussumier describes it as of a citron yellow, with the fins and filaments of a beautiful orange. Buchanan states that the greater number are silvery, with reflections of gold and purple, and a greenish tint upon the back; the fins being then yellow, and the upper parts spotted with black. The same author names the silvery mango-fish *P. risua*, and the yellow ones *P. aureus*; but he hesitates to make them distinct species, and rather opines that the fine colour is the result of season, and that it continues only during spawning time. This view of the subject is well confirmed by the fact, that the high-coloured specimens sent to Europe by M. Dussumier were full either of roe or milt, and is moreover in exact conformity with the observations of all practical anglers and Ichthyologists in relation to the species of our own country. We here figure (Plate CCXCVIII. fig. 11) a recently-discovered species, received by Baron Cuvier from Senegal. It is named *P. quadrifilis*, having only four free rays on the pectoral fins.

In the ensuing genera of the abdominal Percidæ, the ventrals are placed farther back, and the pelvis no longer adheres to the bones of the shoulder.

Genus Sphyræna, Bloch and Sch. Form elongated; two distant dorsals; head oblong, with the lower jaw forming a projecting point beyond the upper one; a portion of the teeth large, pointed, and cutting; opercle without spines; pre-opercle without dentations; seven branchial rays; numerous appendages to the pylorus.

These fish were formerly classed with the pikes; and the Italians still name them *Lucii marini*, on account of their strong and pointed teeth. The Mediterranean species (*S. vulgaris*, Cuv.; *Esox sphyræna*, Linn.) attains to the length of three feet. *S. picuda*, from the coast of Brazil, is extremely similar. This fish, though used as an article of food, is occasionally poisonous. M. Poey alleges that the malady produced by eating it is sometimes mortal; but he adds that it is easy to distinguish the dangerous individuals beforehand, by a peculiar blackness at the base of their teeth. Another species (*S. barracuda*, Cuv.; *Esox barracud*, Shaw), which likewise occurs along the Brazilian shores, and among the Antilles, is said to be extremely formidable, on account of its ferocious habits. It is among the number of those marine monsters of which Rochefort speaks in his *Histoire des Antilles*, as greedy of human flesh. He states it to attain the length of seven or eight feet, and that it darts with fury upon any man whom it perceives in the water.

[1] *British Fishes*, p. 22.

The wounds of its teeth are said to be mortal. Dutertre attributes to it the same great size and malign qualities, and regards it as more dangerous than the fiercest shark. Neither noise, nor any kind of threatening movement, has the slightest effect in producing intimidation; on the contrary, such signs of dislike only excite it to a greater readiness to seize upon its victim. It must be a most disagreeable creature.

Genus Mullus, Linn. Surface of the body and opercles covered by large deciduous scales; pre-opercle without dentations; mouth small, or but slightly cleft, and feebly toothed; dorsal fins distant from each other; a pair of barbles or appendages depending from the symphysis of the lower jaw.

This genus, although allied to the Percidæ by several anatomical and external details, is yet characterised by so many peculiarities of organization, that it might almost be regarded as forming of itself a special family. Cuvier, however, has placed it *à la suite* of the Percidæ, and we shall therefore follow that great authority in this as in the other portions of our ichthyological system. The genus Mullus is now divided into two.

1. Mullus proper. Branchiæ with three rays; opercle spineless; no teeth to the upper jaw; two large plates of small teeth *en pavé* on the vomer; no swimming bladder.

To this sub-genus belongs the famous red mullet (*M. barbatus*), Plate CCXCVIII. fig. 12, which, by reason both of its great personal beauty, and the exquisite flavour of its flesh, has for so many ages ministered to the degenerate and heartless luxury of man. It is very frequent in the Mediterranean, and also occurs occasionally along the outer and more northern coasts of Europe. It is brought occasionally to the London markets during the mackerel season; but it is doubtful whether Müller is not in error in assigning to it so northern a locality as Denmark. "The great and rich among the Romans were in the habit, according to Varro, of preserving the red mullet in artificial waters, as one of the most convincing proofs of their individual wealth. Cicero has ridiculed the senseless ostentation with which they exhibited fine specimens of this fish, domiciliated in their own ponds; but Seneca and Pliny have rendered their countrymen odious in the eyes of posterity, and of other nations, by relating the cruelty with which, in their disgusting orgies, they revelled over the dying mullet, while the bright red colour of its healthy state passed through various shades of purple, violet, blue, and white, as life gradually receded, till the convulsions of death put an end to the *pleasing* spectacle. They had these devoted fish enclosed in water in vessels with sides of crystal, over a slow fire, on their tables, and derived a fiend-like pleasure from the lingering sufferings of their victims as the increasing heat of the water gradually destroyed them, before the final operation of boiling had rendered them fit to gratify the refined taste of civilization. One cannot indeed read these revolting histories of old time without a blush at certain modern practices far too analogous with them: the sense of taste may, in the cases alluded to, be alone consulted; but the difference is nothing to the suffering animal, whether its torments gratify one or more of the evil passions of its tormentors. The skinning of eels, and the boiling of live crustacea, would be as disgusting as the gradual boiling of a mullet, did not, in this as in many other cases, the practice of evil destroy the feeling of its iniquity. So extravagant was the folly of the Romans with regard to this fish, that they often gave for them immense prices. Martial mentions one of four pounds weight, which had cost 1300 sesterces; and it is said that the Emperor Tiberius sold one weighing nearly five pounds for 4000 sesterces. Asinius Celer, one of the consuls, is reported by Pliny to have paid 8000; and, according to Suetonius, 30,000 sesterces had been given for three mullets."[1]

The surmulet, or striped mullet (*M. Surmuletus*, Linn.), is larger than the preceding, and measures about a foot in length. It is much more common as a British species than the preceding, being of frequent occurrence along the extended line of our southern coast, from Cornwall to Sussex; but becoming rarer as we proceed from thence northward by the eastern coast. It has been regarded as migratory, yet it appears in the shops of the London fish-mongers throughout the year, though in much greater plenty during May and June, at which time their colours are most vivid, and the fish, as food, is in the best condition. The striped red mullet spawns in spring, and the young are five inches long by the end of October.[2] The species is much more extensively distributed than the red mullet, and is not confined, as Baron Cuvier seems to suppose, to European coasts. It occurs not far to the south of New York, and has been found in much greater numbers along the southernmost coasts of South America.[3] It has been supposed that to this species the larger specimens of mullet mentioned by the ancients are referrible. Pliny indeed states expressly that the large mullets were found especially in the Northern and Western Oceans.

2. Upeneus, Cuv. Branchiæ with four rays; teeth on both jaws, but frequently none on the palate; opercle with a small spine; a swimming bladder.

The species of this sub-genus are native to the seas of India and America. That which we have selected for illustration (Plate CCXCVIII. fig. 13) is the *H. Vlamingii* of Cuvier. It was sent to Paris by MM. Quoy and Gaymard, and when opened its stomach was found filled with small crustacea.

We here terminate the family of Percidæ, or perch-like fishes, and proceed to

FAMILY II.—BUCCÆ LORICATÆ, or MAILED CHEEKS.

There are a certain set of fishes which, in the totality of their structure, certainly approach the preceding family of the perches; but on which the singular aspect of their variously-armed heads bestows so peculiar a physiognomy, that they have always been classed together in special genera. As examples, we may mention the gurnards, father-lashers, and river bull-heads, belonging to *Trigla* and *Cottus*. The common character of all these fishes consists in the sub-orbital bone being more or less extended over the cheek, and articulating behind with the pre-opercle. The genus *Uranoscopus* alone of the preceding family exhibits some affinity to this form of structure; but still in that case, the sub-orbital, though very broad, is connected posteriorly, not with the opercle, but with the temporal bones. It is then from this peculiar extension and attachment of one or both of the sub-orbitals that the family of the *mailed cheeks* derives its name.

In the Linnæan system these fishes formed three genera, *Trigla*, *Cottus*, and *Scorpæna*, groups which have been considerably subdivided by Cuvier, who has more-

[2] Yarrell's *British Fishes*, p. 27.

[3] Griffith's *Animal Kingdom*, vol. x. p. 278.

over added to them a certain portion of the genus *Gasterosteus*, or stickle-back tribe.

Genus Trigla, Linn. Here the family character is strongly marked. An enormous sub-orbital covers the entire cheek, and even articulates by means of an immovable suture with the pre-opercle, which in this way possesses no separate movement; the sides of the head are nearly vertical, producing a form approaching that of a cube or of a parallelopiped, and the bones are hard and granulated; the back bears two distinct dorsals, and beneath the pectorals are three free rays; in the interior we find about a dozen cæca, and a broad bilobed swimming bladder.

This extensive genus has been subdivided by modern writers.

Trigla proper contains the *gurnards* commonly so called. They have small close-set teeth on the maxillæ, and before the vomer; and their pectoral fins, though large, are incompetent to sustain them through the air. *T. cuculus*, Linn. (*T. pini* of Bloch), our red gurnard, is a voracious species, common in the European seas. *T. lyra*, named the piper, is another British species remarkable for the hissing sound which it produces when caught, by expelling air through its gills. It is a beautiful fish, of a bright red above, and silvery white below. *T. cuculus* of Bloch (*T. Blochii*, Yarrell) is another red gurnard, distinguishable by a black spot on the first dorsal fin. *T. lucerna* is a Mediterranean species, so named because it shines in the dark. *T. hirundo* is a British species, known as the sapphirine gurnard. Its pectoral fins are rich green and blue. The only other species we shall mention is the grey gurnard (*T. gurnardus*), Plate CCXCVIII. fig. 1. Its muzzle is bifurcated, with three spines on each side. It is easily taken with a hook, and is common in the British seas.

Prionites of Lacépède contains species analogous to those last named, but with pectorals so long as occasionally to sustain them in the air. Their precise character, however, consists in their having a band of small close-set teeth on each palatine.

Peristedion of Lac. is separated from Trigla proper, with still more correctness. The whole body is as it were cuirassed over by great hexagonal scales, forming longitudinal ridges; the muzzle is divided into two points, and bears branched barbles beneath; the mouth has no teeth. The only well-known species is the *T. cataphracta*, Linn. a Mediterranean fish, called *Malarmat* both at Marseilles and Genoa, probably by an antiphrase, as it is one of the most redoubtably armed of all the fishes of the European seas.

Dactylopterus of Lac., yet further removed from *Trigla*, contains certain (though not the whole) of those species known under the famous name of flying fishes.[1] Their sub-pectoral rays are much more numerous and extended, and instead of being free, as in the preceding groups, they are united by a membrane so as to form a supernumerary fin, longer than the fish itself, and capable of supporting it in the air.

The common Dactylopterus, or flying fish of the Mediterranean (*Trigla volitans*, Linn.), is a species too remarkable for its functions, so opposite to those of its class in general, not to have attracted from an early period the attention of mankind. It is extremely common in the Mediterranean, and has been mentioned by all the authors who have treated of the fishes of that inland sea. The ardour with which it is pursued by the dolphins and bonitos, the sudden effort which it makes to escape these predaceous creatures by vaulting into the air, the new and probably unthought of dangers which there await it from gulls and other aquatic birds, render it an object of the highest interest to the unaccustomed landsman, somewhat wearied with the monotony of a sailor's life. "It is by the extension of the pectoral rays and membrane that the fish is enabled to raise itself from its proper element to the regions of the air, though this is by no means a continual flight, for the utmost it can do is to describe an arch over the surface of the water extending to a distance of about 120 feet, and sufficiently elevated for the fish sometimes to fall on the deck of a large vessel. This power of flight or momentary suspension would be much greater if the pectoral membrane could preserve its humidity longer: this is soon evaporated in the heat of the tropics; and the membrane, as it becomes dry, loses its buoyant power, and the fish falls. They are sometimes so numerous as to afford much pleasure to the spectator by their repeated flights; and at particular times, especially on the approach of rough weather, in the night, numbers of them may be seen, by the phosphoric light they emit, marking their arched passages in apparent streams of fire.[2]"

It is singular that the species to which we now allude (*D. volitans*), though so frequent in the Mediterranean, should be almost entirely unknown along the oceanic coasts of Europe. Still more singular is it, in relation to that exclusion, that it should at the same time be found across the Atlantic, and spreading not only along all the central and southern shores of the New World, but extending even as far north as the chilly waters of Newfoundland. The great Gulf Stream may however prove influential in the northern distribution of many western species.

We shall conclude this notice by observing, that the fish in question measures about a foot in length; it is brown above, reddish below, with blackish fins, variously spotted with blue. Its most formidable weapon of offence consists of the long and pointed spine of the opercle, which it can raise and render almost perpendicular to its body. With this organ it is easy to conceive that it may produce serious, or even dangerous wounds; and we therefore wonder the less that a poet like Oppian should have declared them mortal.

There seems to be only one other clearly ascertained species of the genus *Dactylopterus*. It is the *D. orientalis* of Cuvier, and occurs in the Indian seas.

Genus Cottus, Linn. Head broad and depressed, mailed, and variously armed by spines or tubercles; two dorsal fins; teeth in front of the vomer, but none on the palatines; six rays to the branchiæ, and only three or four to the ventral fins. The inferior rays of the pectorals, as in the weevers (genus *Trachinus*), are not branched; the cæcal appendages are less numerous than in *Trigla*, and the swimming bladder is wanting.

The fresh-water species of this genus have the head almost smooth, and only a single spine to the pre-opercle. Their first dorsal is very low. The most common is the river bull-head (*Cottus gobio*, Linn.), sometimes called the miller's thumb. It is a small dark-coloured fish, four or five inches in length, and frequent in most of the streams of Europe and the north of Asia. It usually lies concealed beneath stones, from whence it darts with great rapidity upon its prey. It is said to be extremely prolific; and the female, when with spawn, becomes so greatly enlarged, that her ovaries protrude like mammæ. The bull-head, like the salmon, has a reddish hue when boiled. It affords a good and wholesome food, much sought after by the mountain tribes of several countries; yet Pallas as-

[1] Others, for example, belong to *Exocœtus*, one of the genera of *Malacopterygii abdominales*, to be afterwards described.
[2] Griffith's *Animal Kingdom*, vol. x. p. 280.

sures us that in Russia no one will taste it, although the common people hang it around their necks as an amulet, under the impression that it acts as a preservative against attacks of tertian fever. We have represented in this work (Plate CCXCVIII. fig. 2) a salt-water species, *C. scorpius*, commonly called the *father-lasher*, and frequent around our rocky coasts. Under the English name of father-lasher, two species, however, seem to have been confounded.[1] There are many other species of the genus, one of which is extremely common in all the bays and gulfs of Greenland.

Under the generic name of ASPIDOPHORUS, several Cotti have been separated from the parent group. Their bodies are cuirassed by angular plates, and the teeth are wanting on the vomer. Such is a small fish common on our shores, and of which the membrane of the gills is garnished with fleshy filaments. It is the *C. cataphractus* of Linn., our common *Pogge*, or armed bull-head. See Plate CCXCIX. fig. 3.

We may here name three genera as intermediate between *Cottus* and *Scorpæna*, viz. HEMITRIPTERUS (ibid. fig. 4), HEMILEPIDOTUS, and PLATYCEPHALUS. We cannot enter into any details regarding them.

GENUS SCORPÆNA, Linn. Head, as in Cottus, mailed and jagged, but compressed laterally; body covered with scales; seven rays to the branchiæ; a single dorsal fin.

These are small fishes of a repulsive aspect, to be almost inferred from the vulgar names bestowed upon them in most countries, such as scorpion, toad, sea-devil, &c. The species represented on the above Plate, fig. 5, was received from the Isle of France. Many others occur in the Indian seas, as well as in those of more northern countries.

The genus SEBASTES of Cuv. possesses most of the characters of *Scorpæna*, although the head is less jagged and scaly. The species are widely dispersed through both the northern and southern seas. We have selected as an illustration (Plate CCXCIX. fig. 6) *S. variabilis*, which attains to the length of two feet, and occurs in great abundance in the seas about Kamtschatka and the Aleutian Isles, where it is used as food. To this genus belongs another northern species (*S. norvegicus*, Cuv.; the *sea-perch* of Pennant), occasionally found along the British shores, and known to the Shetlanders under the name of *Bergylt*, or *Norway haddock*.[2]

The genus PTEROIS of Cuv. contains the *Scorpæna volitans* of Gmelin and other authors, remarkable for its enormous pectoral fins, which resemble those of the flying fish, except that they are feebler, and, from being so deeply notched, incapable of aiding the fish in leaving its native element. Mr Bennet was assured by the fishermen of Ceylon, where the species is very common, that they had never seen it fly.

The genus APISTUS, Cuv., resembles *Scorpæna* in its palatine teeth and dorsal fin; but the few rays of the pectorals are all branched. The distinguishing character, however, consists in the strong spine of the sub-orbitals, which on being projected from the cheek becomes a dangerous weapon; the more so, as in a state of repose it is scarcely perceptible. In fact, their generic name is derived from ἀπιστος, *perfidious*. M. Ehrenberg has made us acquainted with a species from the Red Sea, which greatly resembles the Indian *Woorah-minoo* described by Russel. It measures about four inches in length, and is of a reddish colour on the back, and whitish on the sides and abdomen. This Apistus flies like a *Dactylopterus*. Ehrenberg observed it in the vicinity of Tor; and whenever the sea was agitated, several fell into his vessel. As it is the only flying fish of the Red Sea, and is extremely abundant along those desert coasts over which the Israelites so long wandered, he has conjectured that the food mentioned in Exodus, ch. xvi. ver. 13, and by us translated *quails*, was in reality the fish in question. It is named by the Arabs *Gherad el bahr*, a term which we understand to signify *sea locust*. The genus is rather numerous. We have figured (Plate CCXCIX. fig. 7) *Ap. marmoratus*, a species transmitted by Peron from Timor. It surpasses the others in size, as well as in the lustre and precision of its marbled markings.

GENUS AGRIOPUS. No sub-orbital spine; dorsal still higher than in the preceding genus, reaching as far forward as between the eyes; the nape of the neck elevated; muzzle narrowed; mouth small and slightly toothed; body without scales.

The fish called sea-horse (*see paard*) by the Dutch colonists at the Cape, and used by them as food, belongs to this genus. It is the *A. torvus* of Cuvier.

GENUS PELOR, Cuv. Dorsal undivided, and teeth on the palate, like Scorpæna; body without scales; two free rays beneath the pectorals; anterior portion of the head appearing crushed; eyes approximate; dorsal spines very high, and almost free; sub-orbital spine wanting.

The fantastic shape and almost monstrous aspect of these fishes are alone sufficient to distinguish them from every other genus. It is scarcely possible by words alone to convey an idea of their extraordinary forms. They inhabit the Indian seas, and one of the most remarkable is *P. filamentorum*, a species from the Isle of France, discovered during Duperrey's expedition. It may be inferred to feed upon crustacea, as the remains of squillæ were found within its stomach.

The genus SYNANCEIA of Bloch and Schneider is quite as hideous as that of *Pelor*, and indeed surpasses all the Scorpænæ in ugliness. Their heads are rough, tuberculated, but not compressed, and frequently enveloped in a loose and fungous skin; their pectoral rays are all branched, their dorsals entire; they have no teeth either on the vomer or palatines.

S. horrida, as the title implies, exhibits by no means an inviting aspect. It is named *Ikan-swangi*, or sorcerer fish, by the Malays. *S. brachio* of Cuv. is the species called *fi-fi*, or *hideous*, by the Negroes of the Isle of France, who hold it in great abhorrence. In fact, nothing can be conceived more frightful. At first sight, no one would consider it a fish, but rather as a mass or unformed lump of corrupted jelly. "Totum corpus," says Commerson, "muco squalidum et quasi ulcerosum." Its head and members seem enveloped in a sack of thick, soft, spongy skin, warty and wrinkled like that of a leper, and irregularly blotted over with various tints of brown and grey. Sometimes it appears entirely black; but it is always gluey and disgusting to the touch. The little eyes are scarcely discernible in the large cavernous head. This species is said to possess great tenacity of life, and survives for a long time out of the water. The skin, in fact, forms a little ring like that of *Pelor*, in the upper part of the gills, above the point of the opercle, through which the fish can respire at pleasure, leaving the remainder of the cover closed, and the branchiæ consequently unexposed to desiccation. The inhabitants of the Isle of France regard it rather as a reptile than a fish; and they fear what they call its sting (that is, the wound inflicted by its spines) more than that of snakes or scorpions.

GENUS MONOCENTRIS, Bloch. Body short, thick, and

---

[1] See *Hist. Nat. des Poissons*, t. iv. pp. 160-165; and Yarrell's *British Fishes*, pp. 60-63.
[2] Fleming's *British Animals*, p. 212.

completely mailed with enormous angular scales, rough and carinated; dorsal fin represented by four or five thick spines; each ventral consisting of a single enormous spine, in the angle of which some small soft rays lie concealed; head large and mailed; front gibbous; mouth large; small and close-set teeth in the jaws and palatines, but none upon the vomer; eight branchial rays.

Of this remarkable genus there is only a single species known, a small fish of a silvery whiteness, measuring about six inches in length. It inhabits the seas of Japan. See Plate CCXCIX. fig. 8.

Genus Gasterosteus, Cuv. Cheeks mailed, but the head neither spined nor tuberculated, as in the preceding genera. The special characters consist in the freedom of the dorsal spines, which do not form a fin, and in the pelvis being united to larger humerals than usual, thus furnishing the abdomen with a kind of bony cuirass. The ventrals, placed posterior to the pectorals, are reduced almost to a single spine. There are only three branchial rays.

The species are small fishes familiarly known under the name of Stickle-backs (Scotice, *Benticles*), extremely common in all the fresh waters of Europe. Gesner indeed asserted that they did not occur in Switzerland; but the contrary has been long since ascertained. Our most common species is *G. aculeatus*, Linn. (Plate CCXCIX. fig. 9), under which name, however, it is supposed that more than a single kind has been confounded. It is an active and greedy little fish, extremely destructive of the fry of other species, and consequently injurious in ponds where these are sought to be preserved. Mr Henry Baker informs us that it will spring not less than a foot perpendicularly out of the water, and to a much greater distance in an oblique direction, when it desires to overcome any opposing obstacle. "It is scarcely to be conceived," he adds, "what damage these little fish do, and how greatly detrimental they are to the increase of all the fish in general among which they live; for it is with the utmost industry, sagacity, and greediness that they seek out and destroy all the young fry that come in their way, which are pursued with the utmost eagerness, and swallowed down without distinction, provided they are not too large; and in proof of this, I must assert that a bannstickle which I kept for some time, did, on the 4th of May, devour, in five hours' time, seventy-four young dace, which were about a quarter of an inch long, and of the thickness of a horse-hair. Two days after it swallowed sixty-two; and would, I am persuaded, have eat as many every day, could I have procured them for it." The stickle-back sometimes swarms in prodigious numbers. Pennant states, that at Spalding, in Lincolnshire, there are once in seven years amazing shoals, which appear in the Welland, coming up the river in the form of a vast column. This concourse is supposed to arise from the multitudes which have been washed out of the fens by the floods of several years, and which collect in deep holes, till, overcharged with numbers, they are obliged to attempt a change of place. The quantity may perhaps be conceived from the fact, that a man employed in collecting them gained for a considerable time four shillings a day by selling them at the rate of a halfpenny a bushel. *G. pungitivus*, commonly called the smaller or ten-spined stickle-back, is the least of all our fresh-water fishes. In common, however, with a more truly marine species (*G. spinochia*, Linn., which forms a sub-genus), it is also found in the sea.[1]

We shall here conclude our exposition of the family with mailed cheeks.

FAMILY III.—SCIÆNIDÆ.

This family is closely related to the Percidæ, and exhibits almost all the same combinations of external characters, especially the dentations of the pre-opercle, and the opercular spines; but the Sciænidæ have never any teeth either on the vomer or palatines; the bones of the face and cranium are generally cavernous, and the muzzle more or less gibbous; a form rarely observed among the Percidæ. The vertical fins are frequently somewhat scaly.

Even in its interior organization our present family bears a considerable resemblance to the perches; but there are greater variations, and especially a more complicated structure of the swimming bladder. In several species that organ is furnished with a multitude of branched appendages (See Plate CCXCVII. figs. 6, 7, 8); and although we cannot trace in it any connection with the exterior, yet when we consider that many of the Sciænidæ are more remarkable even than the gurnards for the production of extraordinary sounds, it is difficult to believe that the peculiar structure of the swimming bladder is not in some way connected with their utterance. The Sciænidæ are almost as numerous as the perches; they are characterised in a great measure by similar habits, and present the same advantages to the human race. They almost all afford excellent eating; of several, indeed, the flavour is exquisite; and a few are of great size. The famous *maigre*, for example (*S. aquila*, Cuv.), commonly weighs about sixty pounds, and sometimes attains to the length of six feet.

A. *Two dorsal fins.*

Genus Sciæna, Cuv. Head gibbous, supported by cavernous bones; two dorsals, or one deeply emarginate, with its softer portion much longer than the spinous; a short anal fin; a dentated pre-opercle; an opercle terminated by points; seven branchial rays.

The species bear a great resemblance to perch, except that they want the teeth upon the palate. Their whole head is scaly, their swimming bladder frequently furnished with remarkable appendages, and the stony bones of the ear are larger than in most fishes. One of the most remarkable is the *maigre* above alluded to (*S. aquila*), called *Umbrina* by the Romans, and held in high esteem even at the present day. (Plate CCXCIX. fig. 10.) It is a rare fish on the outer coasts of Europe, and disappears almost entirely towards the north. The only example with which we are acquainted of its appearance in the northern parts of our own country is recorded by Dr Patrick Neill.[2] It was caught off Ugea in Northmavine, Shetland, in November 1819, and was first observed by the fishermen while endeavouring to escape from a seal. It measured five feet four inches in length, and when lifted into the boat, made its usual "purring sound." Other instances are mentioned by Mr Yarrell. It is, however, extremely common in many parts of the Mediterranean, especially along the Roman states. Paul Jovius mentions that many are taken there at the mouths of rivers, along with sturgeons. They swim in troops, and are said to utter at times a singular low bellowing beneath the waters. It is recorded that three fishermen, guided by this sound, dropt their net on one occasion so successfully as to secure twenty fine fish at a single throw. The noise may be heard at a depth of twenty fathoms, and is often very perceptible when the ear is placed upon the gunnel of the boat. Its tone seems to vary, as some have compared it to a dull buzzing, others to a sharp whistle. Some of the fishermen allege that the

---

[1] It appears that we now possess seven British species of stickle-back, of which the *four-spined* (*G. spinulosus*, Yarrell) was discovered by Dr James Stark in the neighbourhood of Edinburgh. He exhibited specimens to the Wernerian Nat. Hist. Society in 1831.

[2] *Edin. New Phil. Journ.* No. 1.

males alone are musical during spawning time, and that it is quite possible to capture them without any bait, merely by imitating this peculiar sound. One alluded to by Cuvier as having been entangled in a net spread along the shore at Dieppe, was at first found sleeping; but on being handled, it roused itself so suddenly, and with such violence, as to precipitate the fisherman into the water, and force him to call for assistance before he could become its master. High, though of course imaginary virtues, were formerly attributed to the stones which occur in the ear of this, as of other osseous fishes. They were worn on the neck, set in gold; and Belon says they were called *colic-stones*, being renowned for the cure, and even prevention, of that complaint. It was necessary, however, that they should be received as a gift,—such as were purchased being found to lose their virtue.

The species above mentioned belongs to the genus Sciæna proper of Cuvier, a subdivision characterised by the feebleness of the anal spines, and by the want of canine teeth and barbles.

Other subdivisions of the principal genus Sciæna are as follows:—Otolithus and Ancylodon are foreign groups (from India and America), which we shall merely name. Corvina of Cuvier differs from Sciæna proper chiefly in the much greater strength of the second anal spine. An abundant species in the Mediterranean is the *C. nigra*, of a silvery brown colour, with the ventral and anal fins black. It occurs in salt marshes and the sea, but does not appear to ascend rivers. It is less esteemed than the maigre, but is not unfrequently sold for that fish in the Italian markets. Johnius of Bloch is closely allied to the preceding. We here figure as an example of that minor group, the *C. dentex* of Cuv., a species from St Domingo. (Plate CCXCIX. fig. 12.) Several of the fishes used as food in India belong to the genus *Johnius*. Their flesh is light, but not highly flavoured. They are called *whitings* by the English in Bengal. The species are tolerably numerous, and inhabit both seas and rivers. Umbrina of Cuvier is distinguished from the other Sciænæ by bearing a barble on the symphysis of the lower jaw. (Ibid. fig. 11.) The species represented (*U. coroides*) is a native of Brazil. The bearded Umbrina (*U. vulgaris*, Cuv.), a species frequent on the coasts of France, Italy, and Spain, was captured in the river Eye in 1827, as recorded in the minute-book of the Linnæan Society. Pogonias, Lacépède, resembles the preceding; but it is furnished with several barbles instead of one. The species are remarkable for their size, some of them weighing occasionally above a hundred pounds, and for the singular sounds uttered by them, and which have gained them the vulgar name of *drums*. Mr John White, an American lieutenant, who (in 1824) published a Voyage to the China Seas, relates, that being at the mouth of the river Cambodia, himself and crew were greatly astonished by certain extraordinary sounds, which were heard from around and beneath the vessel. They resembled a combination of the base of an organ, the sound of bells, and the guttural cries of a large frog, with certain tones, which the imagination might attribute to a gigantic harp. It might almost have been said that the vessel trembled at those uncertain sounds. For some time they increased, and finally formed a loud and universal chorus, the entire length of the vessel, and on either side. In proportion as they ascended the river the mysterious sounds diminished, and finally altogether ceased. The interpreter gave the information that they were produced by a troop of fishes of a flattened oval form, which possess the faculty of adhering firmly to various bodies by their mouths. A similar phenomenon was noticed by the illustrious Humboldt in the South Seas, although he was unable at the time to divine the cause. It would, as Cuvier has remarked, be an object of curious research to discover by what organ these sounds are produced. We have already mentioned, that the majority of the Sciænidæ, especially such as are the most remarkable for the utterance of the sounds in question, have large swimming bladders, furnished with strong muscles. In some species the organ is characterised by prolongations, more or less complicated, which even penetrate the intervals of the ribs. It must, however, be borne in mind that these swimming bladders have no communication with the intestinal canal, nor in general with any part of the exterior. The example of the genus here figured is *P. fasciatus* (*Labrus Grunniens* of Dr Mitchell), a North American species. (Plate CCXCIX. fig. 13.)

Genus Eques, Bloch. Recognisable by a compressed elongated body, raised at the shoulders, and finishing in a point towards the tail; the first dorsal is elevated, the second long and scaly.

All the known species are American. See Plate CCXCIX. fig. 14.

B. *A single dorsal fin.*

a. *Seven branchial rays.*

The genera of this subdivision are Hæmulon, Diagramma, and Pristipoma, foreign groups, of each of which we have figured an example. See Plate CCC. figs. 1, 2, 3.

b. *Less than seven branchial rays.*

This minor group is again subdivisible in accordance with the character of the lateral line. Those in which that part is continuous to the tail are the genera Lobotes (Plate CCC. fig. 4), Cheilodactylus (ibid. fig. 7), Scolopsides (ibid. fig. 6), and Latilus (ibid. fig. 9). Those in which it is interrupted are Amphiprion (ibid. fig. 5), Premnas (ibid. fig. 8), Pomocentrus (ibid. fig. 11), Dascyllus, Glyphisodon (ibid. fig. 10), and Heliases. All these last-named genera consist of small species, which, with few exceptions, are natives of the Indian seas, the shores of which they embellish by the splendour of their colours, which are in general extremely brilliant. They may be perceived swimming about incessantly, and with great vivacity, among the rocks, and in the watery pools left by the ebbing tide. Although for the most part eatable, none of the species furnishes an important article of consumption, on account of the smallness of their size, and their not occurring in numerous shoals.

FAMILY IV.—SPARIDÆ.

The genera of this family, like those of the Sciænidæ, have the palate destitute of teeth, and in their general forms, as well as in several particulars of their organization, they bear a strong alliance to that family; but they have no scales upon the fins. Their muzzle is not gibbous, nor the bones of their head cavernous. There are no dentations to the pre-opercle, nor spines to the opercle. The pylorus is furnished with cæcal appendages. None of the species possesses more than six rays to the branchiæ. They are further divisible according to the form of their teeth.

Genus Sargus, Cuv. Cutting incisors in front of the jaws, almost similar to those of the human race.

The species in general feed on shells and the smaller crustacea, which they easily crush with their molar teeth. Certain kinds appear to devour fuci, at least Cuvier found the stomachs of some which came from the Red Sea, and of others from the Atlantic Ocean, filled with that marine vegetation. Many vague notices of the Sargi are contained in ancient authors. Ælian and Oppian inform us that the male is polygamous, and fights with great fury against his own sex for the possession of many females.

The same authors attribute to it a feeling still more extraordinary,—a lively passion for goats, which it exhibits by always swimming with great rapidity towards those animals, and indulging in playful gambols before them. So blind was this passion, that a fisherman (it was so alleged) might catch as many as he pleased by disguising himself with the skin and horns of a goat, and scattering in the water flour steeped in goats' broth. We have somewhere seen a doggrel rhyme in allusion to this strange and foundationless fancy (it may have been an attempted translation of an ancient epigram), in which it was expressed that the Sargus

> Went courting she-goats on the grassy shore,
> Horning those husbands who had horns before.

The best-known species inhabits the Mediterranean. It is the *S. Rondeletii* of Cuv. (Plate CCC. fig. 12.) The American shores produce several others, one of which (*S. ovis*) is called the *sheep's-head* by the Americans. Dr Mitchell speaks in the most eulogistic terms of the superexcellence of its flesh, and of the high esteem in which it is held at the tables of New York. It yields in his opinion to few fishes, and is worthy of being served at the most sumptuous entertainments. The price varies from a dollar to a dollar and a half for a middle-sized individual, and above that size the price ranges even so high as from four to seven pounds sterling. They sometimes weigh from fourteen to fifteen pounds. The fishery of this species forms an object of importance along the coasts of the state of New York. It approaches those of Long Island in the hot season from the month of June till the middle of September, after which it seems to seek retirement in the deep abysses of the ocean. As they swim in troops, they may be advantageously fished for with the net, and many hundreds are sometimes taken at a single cast. With the great nets used at Rayner town, and the two islands, thousands are drawn ashore. They are immediately packed in ice, and despatched during the cool of the night to the markets of New York. It is difficult to take the *sheep's-head* with a line, because it contrives to snap the very hooks asunder with its cutting teeth.

Genus Chrysophris, Cuv. Round molars on the sides of the jaw, forming at least three rows on the upper one; a few conical or blunted teeth in front.

The species of this genus are numerous, and extended through many seas. Those of the Mediterranean are only two in number, and are called *Daurades* by the French, no doubt from the Latin *Aurata*, a term applied to them by ancient authors. The Greeks named them Chrysophris, which signifies golden eye-brow, in allusion to the brilliant spot of gold which the common species bears between its eyes. That the *Aurata* of the Latins was identical with the *Chrysophris* of the Greeks, may be inferred from a passage in Pliny, which is obviously borrowed from Aristotle, and where the former word is used as the translation of the latter. According to Columella, the Aurata was among the number of the fishes brought up by the Romans in their *vivaria;* and the inventor of these vivaria, one Sergius Orata, is supposed to have derived his surname from the fish in question. Ælian tells us that the Chrysophris is the most timid of all fishes, and that branches of poplars planted in the sand during a reflux so terrified a party of these fishes which were carried upwards by the flux, that in the succeeding reflux they did not dare to pass the poplars, but allowed themselves to be taken by the hand.

The only species we shall here notice is the *Chrysophris aurata* (Plate CCC. fig. 14), described under the name of *Gilt-head* by Pennant.[1] This fish seldom quits the vicinity of the shore, and grows extremely fat in the salt ponds. We owe to Duhamel whatever information we possess regarding its habits. The fishermen informed that author that it agitates the sand forcibly with its tail, so as to discover the shell-fish which may lie beneath concealed. It is extremely fond of muscles, and its near presence is sometimes ascertained by the noise which it makes while breaking their shells with its teeth. It greatly dreads cold, and many were observed to perish during the severe winter of 1766. The Gilt-head is a British species, but of extremely rare occurrence.

Genus Pagrus, Cuv. Differs from the preceding by having only two rows of small rounded molar teeth in each jaw; the front teeth are either like those of a wool card, or small and crowded.

We have figured the best-known species, *Pagrus vulgaris*, Cuv. (*Sp. pagrus*, Linn.), the braize or becker of English authors, which appears to be confined chiefly to the Mediterranean. (See Plate CCC. fig. 13.) Its synonyms seem confused and contradictory, and are greatly mingled in the works both of British and foreign authors with those of certain *Pagelli* and other Sparidæ. Its history as a British species is obscure. Dr Fleming no doubt records it in his *British Animals*, p. 211; but as he indicates it by "a dark spot at the base of the pectorals," it is probable that his actual species was *Pagellus centrodontus*, Cuv. synonymous with *Sparus orphus* of Linn. Mr Couch, however, observes that it appears on the Cornish coast in moderately deep water throughout the summer and autumn, and retires in winter and spring.[2]

Genus Pagellus, Cuv. Teeth nearly resembling those of Pagrus, but the molars, equally in two rows, are smaller; the conical teeth in front are slender and more numerous; and the physiognomy is different in consequence of a more elongated muzzle.

Several species occur in the European seas. *P. erythrinus*, commonly called the Spanish Bream (Plate CCC. fig. 15), is very abundant in the Mediterranean, and even enters the Atlantic, advancing pretty far north. It is very rare along the British shores. The fish figured by Donovan (*British Fishes*, iv. pl. 89) as the *Sparus aurata* of Linn. (Pennant's Gilt-head) belongs to our present genus. It is the *Pagellus centrodontus* just before referred to, which Pennant also erroneously regarded as synonymous with *Sparus pagrus* of Linn. It is by no means a rare British species, although usually concealed by our modern authors under some other name. It is the *sea-bream* of Couch and Montagu.

Genus Dentex, Cuv. Conical teeth even on the sides of the maxillæ, usually in a single row, and of which some of the anterior are lengthened into large hooks.

The *Dentex vulgaris*, a fish of a silvery hue, shaded into blue upon the back, with reddish pectoral fins, and sometimes attaining to the weight of twenty pounds, has occurred upon the Sussex coast. The specimen figured by Donovan, pl. 73, was obtained in Billingsgate market.

Genus Cantharis, Cuv. Teeth small and closely set all round the jaws, the outer range being the strongest; body elevated and thick; muzzle short; jaws not protractile.

The species of this genus, of which four inhabit the European seas, are very voracious, and easily taken by hook and line. We may name as an example the fish called the black bream by Montagu[3] (*Cantharus griseus*,

[1] The *Gilt-head* of Donovan and Turton is, however, another species, the *Pagellus centrodontus*, Cuv.

[2] *Linn. Trans.* vol. xiv. p. 79.

[3] *Mem. of Wernerian Society*, vol. ii. p. 451.

Cuv.; *Pagrus lineatus*, Fleming; *Sparus brama*, Linn.). Other species occur about the Cape of Good Hope, and in the Indian seas; but it does not appear that any have yet been observed along the American shores, or around the islands of the Atlantic.

The genus Boops,[1] with which we shall conclude our sketch of the Sparidæ, has its outer row of teeth of a trenchant or cutting form; the mouth small, and not at all protractile. Two species occur in the European seas, more particularly in the Mediterranean. They differ from most of their congeners in living entirely on marine plants, such as algæ and fuci of various kinds. In accordance with this vegetable diet, their intestinal canal is very long, though they have few appendages around the pylorus. They are celebrated for the beauty of their colours.

FAMILY V.—MENIDÆ.

The genera of this family differ from those of the preceding in their upper jaw being capable of projection and retraction, in consequence of the length of the intermaxillary pedicles, which withdraw between the orbits. Their body is scaly like that of *Sparus*, of which genus they formed a part, until their re-arrangement by Baron Cuvier.

As we have nothing of general interest to state regarding the fishes of this comparatively limited group, we shall merely refer, in relation to its general contents, to our *Systematic Table* (note to page 165), and proceed to

FAMILY VI.—SQUAMMIPENNES.

So called because the softer, and frequently also the spinous portions of the dorsal and anal fins are covered with scales, which as it were encrust them, and render their discrimination from the rest of the body by no means easy. This is the most obvious character of these fishes, of which the form is in general much compressed. The intestines are rather long, and the cæca numerous. This family was comprised by Linnæus in his genus Chætodon, so called from the long, slender, and hair-like character of the teeth; and the species in general are alike remarkable for their singular forms and splendid colours.

The seas of the torrid zone have indeed no cause to envy the productions of those famous lands, the shores of which they have so long bathed with their translucent waters. If the equatorial regions of Africa and America possess, among their feathered tribes, the brilliant souimangas, the lustrous humming birds, and the gorgeous chatterers, the intermediate ocean and the Indian seas contain countless thousands of the finny race which surpass even these in splendour. The Chætodons, in particular, form a family on which nature has bestowed her ornaments with a most lavish hand. The deep purple of the iris, the paler richness of the rose, the azure blue of the "crystalline sky," the darkest velvet black,—these hues, and many more, are seen commingled with metallic lustre over the pearly surface of this resplendent group. The eye of man receives the greater pleasure from their contemplation, in as far as being of moderate size, and haunting habitually the rocky shores, at no great depth of water, they are seen to sport in the sunbeams, as if desirous to exhibit their splendid liveries to the greatest advantage in the blaze of day.

Tribe 1st. Teeth Hair-like.

Genus Chætodon, Cuv. Body more or less elliptical, the spinous and the softer rays continuing in a nearly uniform curve; muzzle more or less advanced; the preopercle sometimes finely dentated.

The species resemble each other not only in the more essential characters just stated, but even in the distribution of their markings. The majority, for example, are characterised by a black vertical band, in which the eye is placed. In some we find several additional vertical bands parallel to the one mentioned; in others they are oblique or horizontal. Certain species are distinguished by a filament which results from the prolongation of one or more of the soft rays of the dorsal fin. The genus is very extensive, containing upwards of sixty species even in its restricted constitution. We must here confine ourselves to a slight notice of two or three of these. *Chætodon reticulatus*, Cuv. (Plate CCCI. fig. 1) is a beautiful example obtained by MM. Lesson and Garnot at Otaheité. Its sides are mailed or reticulated by a longitudinal series of scales. It measures about six inches in length, and four in height. *Ch. lunula*, Cuv. (ibid. fig. 2), occurs at the Isle of France. It is nearly of the same size as the preceding. A third species, of even more singular markings, is *Ch. Ephippium* of the same author (ibid. fig. 3). It was found at the Moluccas by M. Reinwardt—at Bolabola one of the Society Islands, by MM. Lesson and Garnot,—and appears, by a coloured drawing in the Banksian Library, to have likewise occurred at Otaheité during Cook's third voyage.

Genus Chelmon, Cuv. Separated from Chætodon on account of the extraordinary form of the muzzle, which is long and slender, open only at the extremity, and formed by the inordinate horizontal prolongation of the intermaxillary bone above, and of the inferior jaw. These parts are united for two thirds of their length by a membrane, so that the mouth is nothing more than a small terminal cleft. The teeth are rather fine and closely set than hair-like. *Chelmon rostratus* (*Chæt. rost.* Linn.) is the most anciently known. It is a small fish, measuring from six to eight inches in length, and is remarkable for the following peculiarity. It feeds on flies and other winged insects, and when it perceives one of these either hovering over the surface, or settled on a twig or blade of grass, it ejects against it with considerable force a drop of liquid from ist tubular snout, so as to drive it into the water. In shooting at a sitting insect it generally approaches cautiously within a few feet before it explodes the water. Schlosser has described this curious device in the *Philosophical Transactions* for 1764, after Hummel, and it has since been confirmed by Reinwardt. It is even said to be an amusement of the Chinese in Java to keep this fish in confinement in a large vessel of water, with a view to observe its dexterity in the practice of this admirable instinct. They fasten a fly or other insect to the side of the vessel, when the Chelmon immediately bombards it with such precision as very rarely to miss the mark. In a state of nature it is said to inhabit both the coasts and rivers of Java. We are as yet acquainted with only one other species of this restricted genus. It is the *Ch. longirostris* of Broussonet, of which the reader will find an accurate representation on Plate CCCI. fig. 5. It is not known *de facto* to possess the same singular mode of capturing its prey as the preceding, but that it does so may be almost inferred from its similarity of structure.

Genus Henochius, Cuv. Differs from Chætodon in the spines of the back, particularly the third and fourth, being greatly increased in length, and forming a filament sometimes double the length of the body.

---

[1] The generic name is changed to Box in the *Hist. Nat. des Poissons*, t. vi. p. 346.

Acanthopterygii. Squammipennes.

H. macrolepidotus is a large fish, celebrated in the East for the excellence of its flavour. It is called *Vlagman* by the Dutch colonists, in allusion to the long filament upon the back. They also name it *Tafel-visch*, on account of its frequent use as food. Ruysch asserts that at Amboyna no good dinner is ever served without it, and he compares its taste to that of the finest flounder. The specimens hitherto sent to Europe do not seem to exceed the length of ten inches; but the species must at times greatly exceed that size, if, as Renard and Valentyn assert, it weighs from twenty to twenty-five pounds. As an example of this extraordinary genus we have figured *Henochius monoceros*, a species recently transmitted from the Isle of France by MM. Quoy and Gaimard, Plate CCCI. fig. 4. The specimen represented does not measure above seven inches, and its height is almost equal to its length.

The genus Zanclus of Commerson is closely allied to the preceding, but the scaling is so much more delicate that the skin appears almost smooth to the naked eye. The external aspect is, if possible, still more extraordinary. We have here engraved *L. cornutus* of Cuv. (Plate CCCI. fig. 8), which, on account probably of its singular form and horned front, has become an object almost of superstitious reverence among the fishermen of the Moluccas. It is alleged, that when they happen to capture one of this species, they immediately salute it by certain genuflexions, and then cast it into the sea. It is, however, an excellent table fish, which attains a weight of fifteen pounds, and resembles the turbot in flavour. It is rather widely diffused, occurring both in the Indian seas and Pacific Ocean.

Genus Ephippus, Cuv. Distinguished by a deep emargination between the spinous and softer portion of the dorsal fin; the former part has no scales, and can be folded into a groove on the back.

An American species (*E. gigas*) is remarkable for the great club-shaped enlargement of the first inter-spinal of the anal and dorsal fins, and by a similar enlargement of the crest of the cranium. A fish which may be referred to a subdivision of this genus, occurs among the fossils of Mount Bolca.[1]

Baron Cuvier has remarked,[2] that among all the strange and fantastic fishes preserved in the representations of Ruysch, Renard, and Valentyn,[3] and which have so long excited the mistrust of naturalists, none seems more likely to provoke that feeling than the species which these writers designate by the Malay name of *Skankarbauw*, or buffalo-fish; and yet it now turns out that none is more accordant with the truth of nature. Its sharp recurved horns, the protuberance above the head, the compressed and unequal spines, and the singular distribution of colour, —all exist in a species recently received from the Indian Archipelago. It has accordingly been named Taurichthys by Cuvier,—the Greek translation of the Malay name. The species here figured is *T. varius*, which is from four to six inches long, with a height almost equal to its length. See Plate CCCI. fig. 7.

Genus Holacanthus, Lacép. A large spine at the angle of the pre-opercle, the margins of which are usually dentated.

The species are remarkable for the great beauty and symmetrical distribution of their colours, and for their excellence as articles of food. They are numerous both in the Indian and American seas. One of the most celebrated for the splendour and singularity of its aspect, is that named the *Emperor of Japan* by the Dutch, *Chætodon Imperator* of Bloch, figured in many works. Its body is deep blue, traversed all over by about two and thirty narrow bands of orange yellow.[4] The pectoral fins are black, and the entire tail bright yellow. It is a large fish of its kind, sometimes attaining the length of fifteen inches, and, as an article of food, is one of the most esteemed of all the Indian species, resembling our own much-prized salmon in flavour. Another and more recently discovered species is *H. semicirculatus*, Cuv. It occurs both at Timor and New Ireland. Its colours are white and blue, its length from four to five inches. The inhabitants of Waigiou call it *Mami*.

Genus Platax, Cuv. Anterior to the brush-like teeth, a row of cutting teeth, each of which is divided into three points; body much compressed, and apparently prolonged into thick, greatly elevated, scaly, vertical fins, in the anterior edge of which a small number of spines lie concealed.

Almost all the known species occur either in the Indian or Pacific Oceans. One or two were found by Ruppell in the Red Sea. They are esteemed as food. Words can convey but a feeble idea of the anomalous form of these fishes, some of which, if we include the vertical fins, are more than twice as high as they are long. We here figure the *Chætodon teira* of Bloch, which is a true Platax, Plate CCCI. fig. 6. It was brought by M. Dussumier from the coast of Malabar. It is said to attain to the length of two feet, a great size for a fish of this genus, many of which measure only a few inches. *P. punctulatus*, indeed, may be regarded as one of the smallest of known fishes, as it is only an inch long. It occurs at Timor.

Genus Psettus, Commerson. Form resembling the preceding; but all the teeth are small and crowded, and the ventral fins are reduced to a single small spine, without soft rays.

The species are natives of the Indian seas. Their teeth are rather short and close than in the usual bristle-like form of our present tribe of Squammipennes, yet they cannot be arranged under tribe third, in as far as they want the teeth upon the palate. The *Chætodon rhombeus* of Bloch and Schneider belongs to this genus. It was anciently represented by Seba (t. iii. pl. 26, fig. 21), and now bears the name of *Psettus Sebæ*. The species is extremely rare, and its native country was unknown, till in recent times a specimen was transmitted from the Senegal coast by M. Perottet. It measures six inches in length, and is considerably higher than long. See Plate CCCII. fig. 1.

Tribe 2d. With cutting teeth.

Genus Pimelepterus, Lacép. Distinguished from all other fishes by a single range of teeth borne upon a ho-

---

[1] *Ittiol. Veronese*, plate 5, fig. 2.

[2] *Hist. Nat. des Poissons*, t. vii. p. 146.

[3] The works alluded to above are the following:—1. The *Theatrum Animalium* of Henry Ruysch (son of the celebrated anatomist), two vols. in folio, Amsterd. 1718, which is in fact a third edition of Johnston's prior work of the same name, with the addition of the plates of fishes, to be afterwards noticed. 2. A Dutch work entitled East India, Ancient and Modern, in five vols. folio, Amsterd. 1724-26. The author was Francis Valentyn, a Protestant clergyman of Amboyna. 3. A Collection of Figures of Fish, and other Marine Creatures, published by Francis Renard, in one vol. folio, Amsterd. 1754. This *recueil* was formed about thirty years prior to its publication, and was engraved from a collection of native Indian drawings, which, under a necessarily extraordinary aspect, are now known to exhibit with accuracy many truly interesting species. The same series of drawings, or a corresponding copy, seems to have supplied the originals of both the other works just named.

[4] Shaw describes this magnificent fish as of a "golden-yellow, longitudinally but somewhat obliquely striped with very numerous bright blue parallel rays." This seems in some measure the reverse of the above, but is accounted for by the equal proportion of the two colours, either of which may be regarded as the groundwork.

rizontal base or heel, on the anterior edge of which is a vertical cutting portion. The body is oblong, the head obtuse, and the fins rendered thick by means of the scales with which they are covered.

P. Boscii is a small Atlantic species, which measures about five inches in length. Bosc, by whom it was brought from the coast of Carolina, has seen it following vessels in the high seas, and assembling in troops around the stern, in order to seize upon whatever is thrown overboard. It is shy at seizing a hook, and is said to know how to carry off the bait without being captured. It is sought after as food by the French, though held in slight esteem by the natives of Britain.

The only other genus of this tribe is that named Dipterodon by Lacépède.

Tribe 3d. Teeth either close-set or en carde *on the jaws and palate.*

Genus Brama, Bloch and Schneider. Pertains to our present family, so far as concerns the scales which cover the vertical fins, which have only a small number of spiny rays concealed in their anterior margins; but the teeth are *en carde* on the jaws and palate, the profile elevated, the muzzle very short, the front descending vertically, the mouth almost vertical when closed. The scales reach as far as the maxillaries; there are seven rays to the gills; a low dorsal and anal fin, each commencing by a salient point; a short stomach, a small intestine, and only five cæca.

Of this genus there was known till recently only a single species, that of the Mediterranean, the *Sparus Raii* of Bloch.

It is only of late that its characters and history have been rendered in any way clear or satisfactory—a fact the more remarkable when we consider its large size, its singular form, its extreme abundance, and the exquisite flavour of its flesh. In spite of all these circumstances, most modern authors seem to have written regarding it as if they were blindfolded. Bloch regarded it as a northern fish, simply because so far back as 1681 a specimen was thrown ashore on our Yorkshire coast; and Lacépède describes it as an oceanic species. The individual above alluded to was described by Ray in his Synopsis (p. 115), under the title of *Brama marina cauda forcipata*. Pennant figures and describes it in his British Zoology (2d edition) by the name of *toothed Gilt-head*, and it seems indicated by Mr Couch (in *Linn. Trans.* xiv. 78) as a Chætodon seen off the coast of Cornwall. There is no doubt that its central dominion is in the Mediterranean, as it is extremely common along many coasts of that inland sea.[1] It is called *Rondanin* in the markets of Genoa. At the same time there is no doubt that it wanders occasionally as far north even as Denmark, and that many accidental specimens have been captured along both the British and Irish shores. Two other species have lately been discovered in the equatorial seas.

Genus Toxotes, Cuv. Body short and compressed; dorsal situate on the hinder part of the back, strongly spined, its softer portion, as well as the corresponding part of the anal, scaly; muzzle depressed, short; lower jaw more advanced than the upper; small close-set teeth in either jaw, on the vomer, the palatines, the pterygoids, and tongue; six branchial rays; very fine dentations on the inferior margin of the sub-orbital bone and preopercle. Stomach short and broad; twelve cæcal appendages upon the pylorus; swimming bladder large and thin.

The *Toxotes jaculator* (Plate CCCII. fig. 2) is a small Javanese species, measuring six or seven inches in length, remarkable for possessing the same faculty as that mentioned in our notice of *Chelmon rostratus*. When it perceives a fly or other insect upon an aquatic plant, it dexterously drives it into the water by a shower of drops. Cuvier received a specimen from Batavia, the stomach of which was entirely filled with ants. This species has been erroneously multiplied in systematic works. It is twice described by Shaw[2] under two different names (*Scarus Schlosseri* and *Labrus jaculator*), neither of which is the right one; and there is no doubt of its being identical with Hamilton Buchanan's *Coius chatereus*, a supposed new species from the Ganges.[3] It seems pretty widely distributed throughout the Indian Archipelago, and is known to the Malays by the name of *Ikan-sumpit.*

FAMILY VII.—SCOMBERIDÆ.

One of the most useful to the human race of the entire class of fishes, whether we consider their agreeable flavour, their considerable size, or their inexhaustible productive powers. We may mention the mackerel, the tunny, and bonito, as familiar examples.

When considered isolately, these celebrated fishes are by no means difficult to characterise. The simple separation of the posterior of the second dorsal, and of those of the anal fin, would of itself suffice; but the species above named are the chiefs of a numerous series of genera and sub-genera, in which the more typical form gradually alters, and passes insensibly into others which do not exhibit either the character just mentioned, or almost any other by which the principal types are distinguished. Scales usually very small, causing the greater part of the skin to appear as if entirely smooth; opercular pieces without spines or dentations, and in general numerous cæca;—these are almost the only prevailing characters which can be assigned to the family, which at the same time exhibits a likeness in the aspect of its constituent groups which never leaves it. In short, it forms what botanists call a family by series or transition. The majority have the sides of the caudal extremity carinated, or armed with scales or shields, which are themselves carinated; or the terminal rays of the second dorsal or of the anal are free; or the spiny rays of that dorsal want their uniting membrane. Most frequently the caudal fin is of great size, and corresponding vigour. In the majority, also, the first spiny rays of the anal fin are separated from the others, and form, as it were, a small distinct fin by themselves. But none of these characters is common to the whole.

We may here group, as forming the First Great Tribe, those genera of which the *anterior dorsal fin is entire, but the terminal rays of the posterior one are detached or isolated, forming what may be called finlets or spurious fins* (*pinnæ spuriæ*).

Genus Scomber, Cuv. The mackerels, properly so called, have a fusiform body covered by scales, uniformly small and smooth; sides of the tail not carinated, but merely raised into two small cutaneous crests; a vacant space between the first and second dorsal fin.

The common mackerel (*Sc. scombrus*) is one of the most beautiful of fishes, and too well known to require a

---

[1] Mr Yarrell, however, has brought together various instances of its occurrence along the British shores; and as it is mentioned by Nilsson in his *Prodromus* as occurring on the coast of Norway, and by Reinhardt as a Danish species, it rather appears that Baron Cuvier regarded *Ray's Bream* too exclusively as a Mediterranean species.

[2] *General Zoology*, vol. iv. part ii. pp. 398, 485.

[3] *Fishes of the Ganges*, part 201, plate 14, fig. 34.

Acanthop-terygii. Scomberidæ.

minute description. The back is blue, crossed by many dark transverse bands, nearly straight in the males, but finely waved in the females. The sides and abdomen are of a silvery hue, glossed with brilliant tints of gold. The name is said to refer to the spotted appearance of the upper parts, and to be derived from the Latin *macularius*. We shall here avail ourselves of Mr Yarrell's history of this important species.

"The mackerel was supposed by Anderson, Duhamel, and others, to be a fish of passage, performing, like some birds, certain periodical migrations, and making long voyages from north to south at one season of the year, and the reverse at another. It does not appear to have been sufficiently considered, that, inhabiting a medium which varied but little either in its temperature or productions, locally, fishes are removed beyond the influence of the two principal causes which make a temporary change of situation necessary. Independently of the difficulty of tracing the course pursued through so vast an expanse of water, the order of the appearance of the fish at different places on the shores of the temperate and southern parts of Europe is the reverse of that which, according to their theory, ought to have happened. It is known that this fish is now taken, even on some parts of our own coast, in every month of the year. It is probable that the mackerel inhabits almost the whole of the European seas; and the law of nature which obliges them and many others to visit the shallower water of the shores at a particular season, appears to be one of those wise and bountiful provisions of the Creator, by which not only is the species perpetuated with the greatest certainty, but a large portion of the parent animals are thus brought within the reach of man, who, but for the action of this law, would be deprived of many of those species most valuable to him as food. For the mackerel dispersed over the immense surface of the deep, no effective fishery could be carried on; but, approaching the shore as they do from all directions, and roving along the coast collected in immense shoals, millions are caught, which yet form but a very small portion compared with the myriads that escape.

"This subject receives farther illustration from a fresh-water fish, as stated in the Magazine of Natural History, vol. vii. p. 637: 'When the char spawn, they are seen in the shallow parts of the rocky lakes (in which only they are found), and some of the streams that run into them: they are then taken in abundance, but so soon as the spawning is over, they retire into the deepest parts of the lake, and are but rarely caught.'

"It may be observed farther, that as there is scarcely a month throughout the year in which the fishes of some one or more species are not brought within the reach of man by the operation of the imperative law of nature referred to, a constant succession of wholesome food is thus spread before him, which, in the first instance, costs him little beyond the exercise of his ingenuity and labour to obtain.

"On the coast of Ireland, the mackerel is taken from the county of Kerry in the west, along the southern shore, eastward to Cork and Waterford; from thence northward to Antrim, and north-west to Londonderry and Donegal. Dr M'Culloch says it visits some of the lochs of the Western Islands, but is not considered very abundant. On the Cornish coast this fish in some seasons occurs as early as the month of March, and appears to be pursuing a course from west to east. They are plentiful on the Devonshire coast, and swarm in West Bay about June. On the Hampshire and Sussex coast, particularly the latter, they arrive as early as March; and sometimes, as will be shown, even in February: and the earlier in the year the fishermen go to look for them, the farther from the shore do they seek for and find them. Duhamel says the mackerel are caught earlier at Dunkirk than at Dieppe or Havre: upon our own eastern coast, however, the fishing is later. The fishermen of Lowestoffe and Yarmouth gain their great harvest from the mackerel in May and June. Mr Neill says they occur in the Forth at the end of summer; and Mr Low, in his *Fauna Orcadensis*, states that they do not make their appearance there till the last week in July or the first week in August.

"The mackerel spawns in June; and, according to Bloch, five hundred and forty thousand ova have been counted in one female. I have observed, by the mackerel sent to the London market from the shallow shores of Worthing and its vicinity, that these fish mature and deposit their roe earlier on that flat sandy shore than those caught in the deep water off Brighton. The young mackerel, which are called shiners, are from four to six inches long by the end of August. They are half grown by November; when they retire, says Mr Couch, 'to deep water, and are seen no more that winter: but the adult fishes never wholly quit the Cornish coast; and it is common to see some taken with lines in every month of the year.' Their principal food is probably the fry of other fish; and at Hastings the mackerel follow towards the shore a small species of *Clupea*, which is there called, in consequence, the mackerel mint. I have been unable hitherto to obtain any specimens of this small fish; but, from various descriptions, I think it is probably the young of the sprat. It is described as being about one inch long in July.

"The mackerel as feeders are voracious, and their growth is rapid. The ordinary length varies from fourteen to sixteen inches, and their weight is about two pounds each; but they are said to attain the length of twenty inches, with a proportionate increase in weight. The largest fish are not, however, considered the best for the table.

"As an article of food they are in great request; and those taken in the months of May and June are generally considered to be superior in flavour to those taken either earlier in spring, or in autumn. To be eaten in perfection, this fish should be very fresh. As it soon becomes unfit for food, some facilities in the way of sale have been afforded to the dealers in a commodity so perishable. Mackerel were first allowed to be cried through the streets of London on a Sunday in 1698, and the practice prevails to the present time.

"At our various fishing towns on the coast, the mackerel season is one of great bustle and activity. The frequent departures and arrivals of boats at this time form a lively contrast to the more ordinary routine of other periods; the high price obtained for the early cargoes, and the large return gained generally from the enormous numbers of this fish sometimes captured in a single night, being the inducement to great exertions. A few particulars from various sources may not be uninteresting.

"In May 1807, the first Brighton boat-load of mackerel sold at Billingsgate for forty guineas per hundred—seven shillings each, reckoning six score to a hundred; the highest price ever known at that market. The next boat-load produced but thirteen guineas per hundred. Mackerel were so plentiful at Dover in 1808 that they were sold sixty for a shilling. At Brighton, in June of the same year, the shoal of mackerel was so great, that one of the boats had the meshes of her nets so completely occupied by them, that it was impossible to drag them in; the fish and nets, therefore, in the end, sunk together, the fishermen thereby sustaining a loss of nearly sixty pounds, exclusive of what the cargo, could it have been got into the boat, would have produced. The success of the fishery in 1821 was beyond all precedent. The value of the catch of sixteen boats from Lowestoffe, on the 30th of June, amounted to L.5252; and it is supposed that there was no less an amount than L.14,000 altogether realised by the owners and men concerned in the fishery of the Suffolk coast.[1] In March 1833, on a Sunday, four Hastings' boats brought on shore ten thousand eight hundred mackerel; and the next day two boats brought seven thousand fish. Early in the month of February 1834, one boat's crew from Hastings cleared L.100 by the fish caught in one night; and a large quantity of very fine mackerel appeared in the London market in the second week of the same month. They were cried through the streets of London three for a shilling on the 14th and 22d of March 1834, and had then been plentiful for a month. The boats engaged in fishing are usually attended by other fast-sailing vessels, which are sent away with the fish taken. From some situations these vessels sail away direct for the London market; at others they make for the nearest point from which they can obtain land-carriage for their fish. From Hastings and other fishing towns on the Sussex coast the fish are brought to London by vans, which travel up during the night.

"The most common mode of fishing for mackerel, and the way in which the greatest numbers are taken, is by drift-nets. The drift-net is twenty feet deep, by one hundred and twenty feet long; well corked at the top, but without lead at the bottom. They are made of small fine twine, which is tanned of a reddish-brown colour, to preserve it from the action of the sea-water; and it is thereby rendered much more durable. The size of the mesh is about two and a half inches, or rather larger. Twelve, fifteen, and sometimes eighteen of these nets are attached lengthways, by tying along a thick rope, called the drift-rope, and at the ends of each net, to each other. When arranged for depositing in the sea, a large buoy attached to the end of the drift-rope is thrown overboard, the vessel is put before the wind, and, as she sails along, the rope, with the nets thus attached, is passed over the stern into the water till the whole of the nets are run out. The net thus deposited hangs suspended in the water perpendicularly twenty feet deep from the drift-rope, and extending from three quarters of a mile to a mile, or even a mile and a half, depending on the number of nets belonging to the party or company engaged in fishing together. When the whole of the nets are thus handed out, the drift-rope is shifted from the stern to the bow of the vessel, and she rides by it as if at anchor. The benefit gained by the boat's hanging at the end of the drift-rope is, that the net is kept strained in a straight line, which, without this pull upon it, would not be the case. The nets are shot in the evening, and sometimes hauled once during the night, at others allowed to remain in the water all night. The fish roving in the dark through the water, hang in the meshes of the net, which are large enough to admit them beyond the gill-covers and pectoral fins, but not large enough to allow the thickest part of the body to pass through. In the morning early, preparations are made for hauling the nets. A capstan on the deck is manned, about which two turns of the drift-rope are taken. One man stands forward to untie the upper edge of each net from the drift-rope, which is called casting off the lashings; others hand in the net with the fish caught, to which one side of the vessel is devoted; the other side is occupied by the drift-rope, which is wound in by the men at the capstan. The whole of the net in, and the fish secured, the vessel runs back into harbour with her fish; or, depositing them on board some other boat in company, that carries for the party to the nearest market, the fishing vessel remains at sea for the next night's operation."[2]

Another mode of fishing is with a hook and line, angled with a coarse rod, from a boat under rapid sail. A slice from the mackerel's own body affords an excellent bait, and even a piece of scarlet cloth or leather is often used with great success. The line is weighed down by a heavy plummet; and when the fish are numerous, two men will thus capture from 500 to 1000 in a single day. It is a singular fact, that the common mackerel has no swimming bladder, although that organ is found in several closely allied species. What necessity of nature, Cuvier asks, can require it in the one, and not in the other? What can have produced it? These are great problems, both in the study of final causes, and in the general philosophy of nature.

Genus Thynnus, Cuv. A kind of corslet round the thorax, formed by scales larger and coarser than those of the rest of the body; sides of the tail with a cartilaginous keel between the two crests above mentioned. The anterior dorsal is prolonged almost to the posterior one.

The tunny (*Th. vulgaris*, Cuv.; *Scomber thynnus*, Linn.), (Plate CCCII. fig. 3), is one of the largest fishes of the ocean.[3] When it weighs only a hundred pounds, the Sardinians give it the name of *scampirro*, a diminutive derived from Scomber. When above that weight, and onwards to three hundred pounds, it is called *mezzo-tonno*, or half tunny. The larger individuals frequently weigh a thousand pounds; and Cetti asserts that old males are taken occasionally weighing eighteen hundred pounds.[4] The fishery of the tunny dates from the most remote antiquity; and the city of Byzantium was more especially enriched by it. The shoals which entered the Bosphorus were said to meet near Chalcedon with a white rock, which so terrified them that they turned into the Gulf of Byzantium, now the port of Constantinople. It was, according to Cuvier, in consequence of this abundance of tunnies, that the gulf in question received the name of the *Golden Horn;* and the oracle of Apollo designated Chalcedon as the *City of the Blind*, because its founders did not perceive the inferiority of its site in relation to these valued fish. Gibbon, however, tells us, that "the curve which it describes might be compared to the horn of a stag, or, as it should seem, with more propriety, to that of an ox. The epithet *golden* was expressive of the riches which every wind wafted from the most distant countries into the secure and capacious port of Constantinople." The same prodigious quantities of the tunny are still seen there as in ancient times. According to Syllius, twenty vessels might be filled by a single cast of the net; and they may frequently be taken by the hand without the aid of nets. When ascending towards the port, they may be killed with stones; and even women take them in quantities, merely by suspending a large basket by a cord from the windows.[5] The tunny fishery was of still more ancient practice in the West. The Phœnicians established it at a very early period on the coasts of Spain, both within and beyond the columns of Hercules. It is thus that we find the tunny on the Phœnician medals of Cadiz and Carteia. Its salted preparation was known to the Romans as an esteemed article, under the name of *Saltamentum Sardicum*.

The tunny fishery does not seem to be now carried on

---

[1] "In an interesting and useful sketch of the natural history of Yarmouth and its neighbourhood, by C. and J. Paget, it is stated at p. 16, that in 1823, one hundred and forty-two lasts of mackerel were taken there. A last is ten thousand."

[2] *British Fishes*, p. 121.

[3] We may here note, in regard to the engraved illustrations of the present treatise, that we found it impossible to maintain a proportional size in our figures. Thus the *tunny*, a gigantic species, appears, upon the plate above referred to, as smaller than its neighbour *Toxotes jaculator*, which is scarcely more than half a foot long.

[4] *Histoire Naturelle de Sardaigne*, t. iii. 134, 135.

[5] *De Constantinop. Topographia*, in præf.

at Constantinople on a great or systematic scale, but is chiefly concentrated in the interior of the Mediterranean. The species sometimes wanders along the British shores; and a fine specimen, measuring nine feet in length, was killed in the beautiful Gairloch, opposite Greenock, in July 1831. It is preserved in the Andersonian Museum, Glasgow.

The fish known to navigators under the name of *Bonito* belongs to our present genus. It is the *Th. pelamys* of Cuv. and sometimes occurs along the British shores. It resembles the tunny in form, but is a great deal smaller, seldom exceeding the length of thirty inches. It is celebrated in the tropical seas for its eager pursuit of the flying fish. The bonito of the Mediterranean, however, be it remembered, belongs to the following genus.

Genus Auxis, Cuv. Corselet and pectoral fins as in Thynnus; but the dorsal fins distant, as in Scomber.

We here engrave (Plate CCCII. fig. 5) a species common in the Mediterranean, where it is called bonito, *Auxis vulgaris*, Cuv. It is of a fine blue colour above, with oblique blackish lines. The flesh is red and coarse. We have eaten it during a voyage to Genoa, in the course of which the vessel was followed by a flock for an entire day. We struck them with a small harpoon from the bowsprit. The species seldom exceeds six pounds.

In regard to the genus Pelamys of Cuv.[1] we shall here merely state, that it is distinguished from the tunnies by its strong, separate, and pointed teeth. The vague name of bonito is likewise applied to one of the species, the *Scomber sarda* of Bloch, common in the Mediterranean. The genus Cybium has the body elongated, without corselet, the teeth large, compressed, cutting, in the form of lancets. On the palatines there are only the close-set kind of teeth. The species inhabit the warmer parts both of the Atlantic and Pacific Oceans, and some of them attain a great size. The genus Thyrsites differs from the preceding in having the anterior teeth longer than the others, as well as the palatines being furnished with pointed teeth.

The genus Gempylus is allied in many respects to that last named, but it wants the teeth upon the palate, and the ventrals are almost imperceptible. See Plate CCCII. fig. 6, where we have represented *G. prometheus*, Cuv., a species discovered at St Helena, by Messrs Quoy and Gaimard.

We shall here briefly notice two genera which cannot be better placed than in succession to the preceding Scomberidæ. We allude to Lepidopus and Trichiurus,[2] which resemble the two last-named groups in almost every thing, except that they entirely want the finlets, or false fins, and even the soft rays of the dorsal. There is merely a vestige of the ventral fins. It is a singular thing, as Cuvier has observed, that a fish so generally met with as the great *Lepidopus argyreus* of the European seas (there is no other species), so handsome, and so large, should have remained unknown to naturalists so recently as the end of the eighteenth century, and that it should have been afterwards successively described by various writers, under a new name, and by each in ignorance of the labours of his predecessor. If we figure to ourselves a large and broad riband of silver, swimming with a wavy motion through the water, and casting from it in its progress the most beautiful reflections of light, we may form some notion of the general aspect of this creature in its living state. Its length, as described by Montagu[3] (under the name of *Zipotheca tetradens*), was five feet six inches, with a depth at the gills of four inches and a half; it gradually decreased from the vent to the commencement of the anal fin, where it measured only two inches in depth; at the end of that fin the form was nearly round, and the diameter only half an inch. The weight, without the intestines, was about six pounds. Montagu's specimen was taken in Salcomb Harbour, on the coast of South Devon, on the 4th June 1808. It was swimming with astonishing velocity, *with its head above water*, going, as the fishermen said, "as swift as a bird," and was killed by the blow of an oar. It occurs occasionally on most of the European coasts; is more frequent in some parts of the Mediterranean; and has been captured as far south as the Cape of Good Hope. See our representation on Plate CCCII. fig. 4.

Acanthopterygii. Scomberidæ.

The other genus to which we have alluded, that of Trichiurus, Linn., resembles the preceding in its head and teeth, but it has not even a vestige of a ventral fin; the anal is replaced by a series of very small spines, which scarcely project above the skin, and the tail terminates in a filament or lengthened point, without any caudal fin. We here figure (Plate CCCII. fig. 8) an Indian species, named *Trichiurus savala* by Cuvier. We believe it is synonymous with *T. armatus* of Mr Gray's *Illustrations of Indian Zoology*. Some additional species are figured in Mr Griffith's valuable edition of the *Animal Kingdom*, and that called the silvery hair-tail, or blade fish (*T. lepturus*, Linn.), was some years ago cast ashore on the Moray Firth.[4]

Another group of Scomberidæ, or rather a branch of the first great tribe, contains the sword-fish, and a few other species, which modern Ichthyologists, anterior to the time of Cuvier, placed too much apart from each other, solely because some were possessed of ventral fins, while in others those parts were wanting, "différence," observes our author, "qui ne sert qu'à prouver de plus en plus le peu d'importance de ces nageoires pour un méthode naturelle."[5] Their relationship to the tunnies and mackerels has been still less appreciated, although very obvious in the form of the tail, the structure of the intestines, the quality of the flesh, and even in the parasitical animals by which they are infested; but as they differ in wanting the false fins, all actual resemblances have been set aside, at least in regard to such as are destitute of ventral fins.

Genus Xiphias, Linn. Pertains to the family Scomberidæ, and approaches the tunnies especially in the extreme smallness of the scales, the carination of the sides of the tail, the strength of the caudal fin, and the whole of the interior organization. The distinctive character consists in the lengthened beak or sword-like prolongation of the muzzle or upper jaw, which forms a powerful weapon of offence, and enables them to attack and overcome the largest marine animals. This beak is composed chiefly of the vomer and intermaxillaries, strengthened towards the base by the ethmoid, the frontals, and maxillaries. The branchiæ are not divided like the toothing of a comb, but formed each of two large parallel plates, of which the surface is reticulated. The rapidity of their course is excessive, the quality of their flesh excellent.

Such is a brief indication of the characters of the genus *Xiphias* of Linnæus, which has been divided as follows, in more recent times.

1*st*. Genus Xiphias proper, Cuv. No ventral fin.

---

[1] *Hist. Nat. des Poissons*, t. viii. p. 149. The genus Pelamys corresponds to that named Sarda in the second edition of the *Règne Animal*, t. ii. p. 199.

[2] Both genera were formerly placed by Cuvier in the ensuing family Tænioidæ. (See *Règne Animal*, t. ii. p. 217.)

[3] *Memoirs of the Wernerian Nat. Hist. Society*, vol. i. p. 82.

[4] *Linn. Trans.* vol. xi. p. 200.

[5] *Hist. Nat. des Poissons*, t. viii. p. 254.

The only known species seems to have received the same name from all nations. *Gladius*, *Epée*, *Dard*, *Pesce-spada*, *Schwerd-fish*, *Sword-fish*, and the Greek generic name of *Xiphias*, all indicate the formidable weapon with which the front is armed. So remarkable a creature in size and structure could indeed have scarcely remained unknown at any period. All ancient writers within whose province it could possibly fall, speak of it in such a manner as clearly to prove an intimate knowledge of its nature. They describe its offensive weapon, the blows which it inflicts, the dreadful combats which it sustains, the attacks which are made upon it, and the stratagems by which, in spite of its strength, it is lured to its destruction. Although, in relation to its European distribution, the Mediterranean may be said to be its chief dominion, yet the older individuals especially often enter the ocean, and astonish the natives of colder climes by spreading along the northern shores. It has been frequently captured on the British coasts. It even enters the Baltic, and has been seen near Lubeck, of an enormous size.[1] Pennant is doubtful of its occurrence as a North American species, although it is named as such by Catesby. It is not noticed by Dr Mitchell, in his description of the fishes of New York, and for this reason Baron Cuvier does not admit that it crosses the Atlantic. It is, however, fully described by Dr Smith, in his *Fishes of Massachusetts;* and the same writer assures us, on the authority of an old pilot, that the sword-fish is by no means uncommon off that portion of the American shore. It cannot, however, be traced far south in any part of the western world; whilst, like many of the Mediterranean species, it advances along the African coast as far as the Cape of Good Hope.

The fish now alluded to is the *Xiphias gladius*, Linn. (Plate CCCII. fig. 7.) Its horizontal snout is flat and cutting, like the blade of a sword. The sides of its tail are strongly carinated. It has but one dorsal fin, which rises both before and behind, but of which the middle portion in the adults becomes in some manner so worn away, that an appearance is at last presented of two dorsal fins. This will be perfectly understood by comparing the figure last referred to, with fig. 10 of the same plate, where we have represented the young of the present species.[2]

Sword-fish, though by no means uncommon, are seldom captured, owing to their extreme vigilance. Captain Beechey informs us, that while in the Pacific Ocean, near Easter Island, "as the line was hauling in, a large sword-fish bit at the tin case which contained our thermometer, but fortunately failed in carrying it off." Their mode of capture in the Mediterranean may be likened to whale fishing in miniature, and is said to be a very amusing and exciting sport. A watchman placed upon a mast, or standing on the summit of a neighbouring rock, gives warning by signal when he sees a fish approach. The fishermen then row towards it; and, being so skilful as frequently to strike the fish from a great distance, they throw a harpoon into it attached to a long line. An arduous struggle then commences, during which the aggressors are sometimes pulled about by the fish for many hours before they can get it into the boat.

We shall conclude by observing, that the sword-fish is not only one of the largest species of the European seas, attaining sometimes to a length of fifteen feet, but that it is also much esteemed as an article of diet. When young, especially, the flesh is white, firm, and of excellent flavour.

2*d*. Genus Tetrapterus, Rafinesque.[3] Point of the muzzle shaped like a stiletto; ventrals consisting each of one unjointed slender bone; two small projecting crests, like those of the mackerel, at each side of the base of the caudal fin.

The sole European species is *T. belone* of the Italian author. It is a large Mediterranean species, of about six feet in length, and weighing from 150 to 200 pounds.

3*d*. Genus Makaira, Lacép. Possesses the points of the two small caudal crests of the preceding genus, but it wants the ventral fins.

We shall merely mention as an example the *X. Makaira*, or short-snouted sword-fish of Shaw.[4]

4*th*. Genus Histiophorus, Lacép. Characterised by the beak and caudal crests of Tetrapterus, but the dorsal fin is so greatly elevated as to serve as a sail when swimming on the surface, and the ventrals are long, slender, and composed of two rays.

This genus contains that large and showy species (*H. indicus*, Plate CCCII. fig. 9) known to the Malays by the name of fan-fish, and called by the corresponding title of sail-fish by the Dutch. It sometimes attains to so great a size as to have been compared to a small whale. When swimming near the surface, its dorsal fin may be seen projecting, from the distance of a league at sea. Many years ago a letter was addressed to Sir Joseph Banks by the captain of an East Indiaman, containing an account of the astonishing strength occasionally exerted by this species. The bottom of the ship was pierced through by it in such a manner that the snout or sword was buried almost to its base, and the animal itself was killed by the violence of the blow. Accidents of a similar nature have also occurred with the common sword-fish; and it is the opinion of naturalists that both species mistake our wooden walls for the vast abdomen of some great cetaceous animal which they desire to encounter and destroy.

We here figure, under the name of *Histiophorus pulchellus*, a beautiful dwarf species taken by M. Raynaud on his return from the Cape to France in 1829. It measured only four inches in length, and possesses certain special characters, which lead to the conclusion that, notwithstanding its minute size, it ought not to be regarded as the young of any previously described species. See Plate CCCII. fig. 11.

We now enter upon a group of genera which form the Second Great Tribe of Scomberidæ, and are characterised by having the *spiny rays of the back not continuous, but separate.*

The Scomberidæ, as has been already remarked, have the caudal fin in general very strong, although the other vertical fins are often extremely feeble. We have now noticed

---

[1] Captain Crow, in a work recently published, relates the following spectacle, witnessed during a voyage to Memel. "One morning, during a calm, when near the Hebrides, all hands were called up at three A. M. to witness a battle between several of the fish called thrashers, or fox-sharks (*Carcharius vulpes*), and some sword-fish on one side, and an enormous whale on the other. It was in the middle of summer, and the weather being clear, and the fish close to the vessel, we had a fine opportunity of witnessing the contest. As soon as the whale's back appeared above the water, the thrashers, springing several yards into the air, descended with great violence upon the object of their rancour, and inflicted upon him the most severe slaps with their long tails, the sound of which resembled the reports of muskets fired at a distance. The sword-fish, in their turn, attacked the distressed whale, stabbing from below; and thus beset on all sides, and wounded, when the poor creature appeared, the water around him was dyed with blood. In this manner they continued tormenting and wounding him for many hours, until we lost sight of him; and I have no doubt they in the end completed his destruction." (Quoted from Mr Yarrell's *British Fishes*, p. 144.)

[2] It was probably this disparity of the dorsal fin in different individuals that induced Dr Leach to apply the new name of *Xiphias Rondeletii* to the old species. (See *Wernerian Memoirs*, vol. ii. part i. p. 58.)

[3] *Caratteri di alcuni nuovi generi*, &c. *della Sicilia*, p. 54.

[4] *General Zoology*, vol. iv. part i. p. 104, pl. 16.

the genera of the first great tribe, in which the posterior portion of the second dorsal and of the anal fin possess no continuous membrane between its rays, which thus remain free and disconnected, under the name of finlets. But in the group which we are about to enter it is the anterior dorsal which wants the membrane, and of which the rays are consequently free, and capable of isolated movement. Certain species even conjoin with this character that of the preceding tribe, and have finlets behind, at the same time that they possess free rays upon their anterior portion.

GENUS NAUCRATES, Rafin. Dorsal spines free; body fusiform; a carina or keel on the sides of the tail, as in the tunny, and two free spines before the anal fin.

This genus contains *N. ductor*, the famous *pilot-fish* of navigators (*Gasterosteus ductor*, Linn.), so named from its habit of keeping company with ships at sea, and frequently swimming beneath their bows. It would seem, from early indications of a similar instinct, to be the *Pompilius* of the ancients, described as pointing out the way to dubious or embarrassed sailors, and as announcing the vicinity of land by its sudden disappearance. It was thus regarded as a sacred fish. The other story of its serving as a guide to the shark does not appear to have been transmitted to us from so remote a source. It is not mentioned even by the Ichthyologists of the sixteenth century; and Cuvier regards as the first allusion to it, that of Dutertre in his *Description of the Antilles*, printed in 1667. Since that period it has been carefully repeated by all voyagers and compilers; and Osbeck even makes it a subject of pious reflection on the wonderful ways of Providence. We are told by a greater than Osbeck that "they that go down to the sea in ships, that do business in great waters; these see the works of the Lord, and his wonders in the deep:" but the fact in the present instance seems reducible to this, that the pilot accompanies both ships and sharks, sometimes swimming before, sometimes behind, for the sake of preying upon whatever may be thrown over board in the one case, or left uneaten in the other. It is true that the shark never attacks it; but it is also true that the hawk does not attack the swallow; and in both instances the reason is the same; the pilot being too nimble for the unwieldy shark in the water, just as the feebler but more agile bird is too swift in its movements for *falco* in the air. It is thus that the apparent alliance of these dissimilar fishes may be explained even upon general principles, to say nothing of Bosc's observation, who assures us that he has seen hundreds of pilot-fish, that they always keep at a respectful distance from the shark, and swim about swiftly in different directions, that they may more certainly avoid it. If any food be thrown over board, the pilot stops to seize it, and abandons both the shark and vessel. Geoffroy no doubt tells a story of two pilot-fish having been seen to take a great deal of trouble, swimming to and fro, in order to conduct a shark towards a *baited* hook; but admitting the truth of the details, it is clear, that whatever advantage might eventually accrue to the conductors, the probable result to the shark was a cruel death, and one is consequently the more inclined to admire how the narrative itself should find place in a Memoir *Sur l'affection mutuelle* des quelques animaux![1]

The pilot-fish in question is chiefly a Mediterranean species, although it also spreads into distant oceans, having been found by Daldorf under the equator. A great extent of geographical distribution may indeed be expected in reference to a species which is said to suffer itself to be led away immense distances in its eager pursuit of ships. Dutertre records that he saw one which followed his vessel for more than 500 leagues. Whether he kept his eye upon it night and day during all that time, or in what other way he ascertained it to be the same individual throughout so long a traverse, is what he does not state, and we therefore cannot explain. "In the year 1831," Mr Yarrell observes, "two specimens of pilot-fish were caught on the opposite side of the British Channel, and more than one instance has occurred of their following ships into Guernsey. A few years since, a pair accompanied a ship from the Mediterranean into Falmouth, and were both taken with a net. In January 1831, the Peru, Graham master, put into Plymouth, on her voyage from Alexandria for London, after a passage of eighty-two days. About two days after she left Alexandria, two pilot-fish, *Gasterosteus ductor*, made their appearance close alongside the vessel, were constantly seen near her during the homeward voyage, and followed her into Plymouth. After she came to an anchor in Catwater, their attachment appeared to have increased; they kept constant guard to the vessel, and made themselves so familiar, that one of them was actually captured by a gentleman in a boat alongside, but, by a strong effort, it escaped from his grasp, and regained the water. After this the two fish separated; but they were both taken the same evening, and, when dressed the next day, were found to be excellent eating. In October 1833 nearly one hundred pilot-fish accompanied a vessel from Sicily into Catwater, but they were not taken."[2] The pilot-fish is of a silvery blue colour, paler below, with

[1] *Annales du Mus. d'Hist. Nat.* t. ix. p. 469. In further illustration of the subject, we shall subjoin a short extract from a recent publication, Dr Meyen's *Reise um die Erde.* "The pilot swims constantly in front of the shark; we ourselves have seen three instances in which the shark was led by the pilot. When the sea-angel neared the ship, the pilot swam close to the snout, or near one of the breast fins of the animal; sometimes he darted rapidly forwards or sidewards, as if looking for something, and constantly went back again to the shark. When we threw overboard a piece of bacon fastened on a great hook, the shark was about twenty paces from the ship. With the quickness of lightning the pilot came up, smelt at the dainty, and instantly swam back again to the shark, swimming many times round his snout, and splashing, as if to give him exact information as to the bacon. The shark now began to put himself in motion, the pilot showing him the way, and in a moment he was fast upon the hook. Once we watched a pilot for many days, who kept constantly swimming close before the keel of the ship. The sailors say, as of a thing well known and familiar, that such a fish so situated has lost his shark, and is seeking another. Upon a later occasion, we observed two pilots in sedulous attendance on a blue shark, which we caught in the Chinese Sea. It seems probable that the pilot feeds on the shark's excrements, keeps his company for that purpose, and directs his operations solely from this selfish view." On this very singular subject we are tempted to quote another anecdote, which, notwithstanding what we have said in the text above, if correctly observed and recorded, would certainly indicate something remarkable in the association of these species. The account was furnished to the editor of the English edition of the *Animal Kingdom* (vol. x. p. 636), by Colonel Hamilton Smith, an accurate and accomplished naturalist. "Captain Richards, R. N., during his last station in the Mediterranean, saw on a fine day a blue shark, which followed the ship, attracted perhaps by a corpse which had been committed to the waves. After some time a shark-hook, baited with pork, was flung out. The shark, attended by four pilot-fish, *Scomber ductor*, repeatedly approached the bait; and every time that he did so, one of the pilots, preceding him, was distinctly seen from the taffrail of the ship to run his snout against the side of the shark's head, to turn it away. After some farther play, the fish swam off in the wake of the vessel, his dorsal fin being long distinctly visible above the water. When he had gone, however, a considerable distance, he suddenly turned round, darted after the vessel, and before the pilot-fish could overtake him and interpose, snapped at the bait and was taken. In hoisting him up, one of the pilots was observed to cling to his side until he was half above water, when it fell off. All the pilot fishes then swam about awhile, as if in search of their friend, with every apparent mark of anxiety and distress, and afterwards darted suddenly down into the depths of the sea. Colonel H. Smith has himself witnessed, with intense curiosity, an event in all respects precisely similar."

[2] *British Fishes*, p. 151.

bands of deeper blue upon the upper portions. It varies from four inches to a foot in length, and the larger individuals have much the aspect of a mackerel. The name of *pilot* has been bestowed on various other fishes, and the genus Naucrates itself contains several species. *N. Indicus*, Cuv. was brought from Amboyna by Messrs Lesson and Garnot.

Other genera of this tribe are ELACATE, LICHIA, CHORINEMUS, and TRACHINOTUS, which we cannot here do more than name.

GENUS RHINCHOBDELLA, Bl. and Schn. Free spines on the back, as in the preceding genera, and two free spines in front of the anal fin, but the ventrals are absent, as in *Xiphias proper*. The body is lengthened.

Of this genus Cuvier has formed two minor groups,—RHINCHOBDELLA (*Macrognathus*, Lacép.), including such species as have the muzzle concave, and striated beneath, and the three vertical fins separate; and MASTACOMBLUS, Gronovius, containing such as have the muzzle simply conical, neither striated nor concave, and the vertical fins more or less completely joined.

The species of both genera inhabit the fresh waters of Asia, and are widely distributed, from Syria to the isles of Sunda, the Moluccas, and China. Their snouts are furnished with a delicate organ of touch, and it appears that they employ it while searching in the mud for small worms, or other slender substances on whieh they feed. They are generally regarded as *poissons de bon gout*, the flavour of their flesh bearing some resemblance to that of eels.

The genus NOTOCANTHUS (of which *N. Nasus* is the sole species) is characteristic of the most northern seas.

We next proceed to a group of the Scomberidæ which forms the THIRD GREAT TRIBE, distinguished by having *the sides furnished with a cuirassed lateral line.*

In the tunnies, sword-fish, and other Scomberidæ already discussed, a projecting cartilaginous portion is observable, forming a kind of ridge or keel on each side of the tail, at the extremity of the lateral line. In the genera of the same family of which we have now to treat, this ridge is no longer a simple prominence of the dermis, but is covered by scaly shields, themselves crested, and overlapping each other. These shields, frequently ending in a point or hook, are not always confined to the termination of the lateral line, but sometimes spread over its entire length, and usually occupy a considerable portion. In relation to this character, however, the tribe may be divided into two sections: the first of which, comprising only the great genus *Caranx*, exhibits this kind of armour in its greatest strength and extension; while the second (of which the genus *Vomer* is the type) shows its gradual reduction to small scales, not surpassing those of the rest of the body.

GENUS CARANX, Cuv. Lateral line armed to a greater or less extent with scaly shields, raised into a keel, and pointed.

As an example, we here figure the *Caranx boops*, a beautiful fish from Amboyna, of a fine silvery hue, tinted towards the back with brilliant steel blue, with green reflections. A pure line of orange extends from the gills to the tail, but this ornamental character is said to disappear speedily after death. The pectoral fins are likewise orange. It varies from a few inches to a foot in length. See Plate CCCII. fig. 12. The genus is extremely numerous, containing probably not fewer than seventy different kinds; but the only other species we shall here notice is a fish called the *scad*, or horse-mackerel (*Caranx trachurus*, Lacép. and Cuv.), which occasionally occurs in prodigious shoals along the British shores. Ten thousand have been taken by a foot-sean in a single evening in August. It likewise occurs in the Mediterranean, and in the vicinity of Madeira.

Of genera allied to CARANX, and consisting chiefly of species heretofore and erroneously referred to ZEUS, Baron Cuvier has established or retained the following, viz. OLISTUS, SCYRIS, BLEPHARIS, GALLICHTYS, ARGYREYOSUS, VOMER, and HYNNIS. Of these our restricted limits prevent our exhibiting the detailed characters. We shall merely present the reader with a figure of that singular little fish *Gallichtys Ægyptiacus*, brought by Ehrenberg from the neighbourhood of Alexandria. It measures only from one to two inches in length, and is of a truly remarkable form. See Plate CCCIII. fig. 1.

We have now arrived at the concluding group or FOURTH GREAT TRIBE of the Scomberidæ, in which *the finlets, the free spines of the back, and the armour of the sides of the tail, are all wanting.*

The genera of this tribe, it will be perceived, are combined by means of merely negative characters, and it may therefore be expected that they will exhibit mutual relations of a less intimate kind than those of the preceding tribes. They form in fact a group, as it were, by continuity,—one of those series of which there are many in nature, and of which the agreement is not the less evident and harmonious, although it may be difficult to point out a precise character in common.

As we have little to say of general interest regarding their history or habits, we think it more suitable to the nature of this article to reserve a principal portion of our allotted space for the elucidation of those species concerning which some important or amusing information has been recorded. We shall therefore do little more than name the genera of our present tribe.

The genus SERIOLA scarcely differs from *Caranx*, except in the lateral line being either unprovided with a cuirass, or at least merely furnished with scales which slightly surpass those of the rest of the body. *S. Dumerilii* of Risso occurs near Nice, and elsewhere in the Mediterranean. It sometimes attains to the great weight of nearly 200 pounds, and dwells in deep and inaccessible places of the sea, rarely approaching the shores, unless when compelled to do so by hunger. Its flesh is of a reddish colour, firm, and of an exquisite flavour.

The genus TEMNODON greatly resembles the preceding, but its teeth are cutting. There are two small spines in advance of the anal fin, but almost concealed beneath the skin. We here place the *Perca saltatrix* of Linn. called *skip-jack* by the Americans. Its geographical distribution is extremely extensive.

The genus NOMEUS, Cuv. was for a long time combined with the Gobies. It is related in several particulars to *Seriola*, but the very large broad ventrals, attached to the body by their inner edge, produce a peculiar character and aspect. We here figure a small species, of which the ground colour is like brilliant silver. The ventrals are traversed by two black bands. It was transmitted to the Museum of the Low Countries from Java, by MM. Kuhl and Van Hasselt. See Plate CCCIII. fig. 4. Three other genera are described by Cuvier in this portion of his great work,[1] which, however, we shall merely name,—viz. NAUCLERUS, PORTHONEUS, and PSENES. The next genus is of more general interest.

GENUS CORYPHÆNA, Linn. Body compressed, elongated, covered by small scales; head compressed, profile circular; eyes low, approaching the angle of the mouth; dorsal fin rising from the cranium, and stretching con-

[1] *Hist. Nat. des Poissons*, t. ix. pp. 247-67.

tinuously to the tail, towards which it decreases in elevation.

This noted genus has been remodelled in recent times, and now consists of the following minor groups.

1*st.* Genus Coryphæna proper. Cuv. Head very elevated, profile curved and perpendicular, eyes low; mouth well cleft; teeth like those of a wool card.

The generic term is derived from κορυφη, *vertex*, or top of the head, in reference to the height of the crest of the cranium. This division contains the famous *dolphin* of the Mediterranean (*Cor. hippurus*, Linn.), so celebrated for the beauty of its versatile tints.

> .... parting day
> Dies like the dolphin, whom each pang imbues
> With a new colour as it gasps away,
> The last still loveliest, till—'tis gone—and all is gray.

The species are still in some measure indistinctly characterized. They occur in the Pacific and Atlantic Oceans, and the Mediterranean Sea, and are remarkable, among other things, for their keen pursuit of flying fish, which, in the first place, they force to leave their native element, and then following swiftly in a corresponding track, receive with open mouth the moment they descend exhausted to the surface. The Coryphænæ may be regarded as among the most brilliant inhabitants of the sea. It is necessary, according to Bosc, to have seen them following a vessel in troops, before we can form a proper estimate of their beauty. When they swim embodied near the surface, and beneath the light of a cloudless sky, they seem effulgent with the richest gold, combined with the sparkling lustre of the topaz, the emerald, and the sapphire,—and every brilliant hue in perpetual change, accordant with the vivacity and varied grace of their movements. It is indeed a spectacle sufficient anywhere to excite our unfeigned admiration; and when seen suddenly amid the waves of the lonely and monotonous ocean, it comes upon us like a glad surprise. The beauty of these fishes has in every age attracted the wonder

> Of all who on the wide deep wandering are;

and it is so far to be regretted, that their fugitive colours have been the chief object of attention,—their more precise description and specific discrimination having been greatly disregarded.

The Coryphænæ are strong, active, and voracious fishes. While swimming rapidly, they seem rather as if impelled or projected forwards by some exterior force, than by any exertion of their own. But, on attentive examination, a strong and rapid muscular movement may be detected, by the constant undulation of the long dorsal fin, a movement which greatly contributes to the throwing off of those lustrous metallic reflections for which they have so long been noted. The Mediterranean species, *Cor. hippurus*, if not the most beautiful, is the largest known. It sometimes attains to the length of five feet. Its colours, so far as they are capable of description, are silvery blue above, with markings of a deeper azure, and reflections of pure gold—the lower parts citron yellow, marked with pale blue. The pectoral fins are partly lead colour, partly yellow; the ventrals are yellow on their under surface, and black above; the anal fin is yellow. The iris of the eye is made of apparent gold.[1]

One or two other kinds, not so distinctly known, occur in the Mediterranean, and many others in more distant seas. We here figure a large species, measuring nearly four feet in length, taken by M. Dussumier about fifty leagues to the west of the Azores, for which reason it bears the name of *Coryphæna Azorica*, see Plate CCCIII. fig. 2. The Portuguese name more than one species *Dorade*, a term which, from its similarity to *Daurade* (a frequent appellation of our gilt-head, *Chrysophris aurata*), has produced some confusion. Not less ambiguous is the name of *Dolphin*, which appears to have been first misapplied to the Coryphænæ by the Dutch. It is scarcely necessary to observe, that the English word Dolphin, as synonymous with the Greek Δελφις, the Latin Delphinus, and the French Dauphin, was originally, and is still correctly, applied only to designate a group of cetaceous animals (allied in structure to the whales), to which the classical dolphin of antiquity assuredly belonged. But by some conversion, into the history of which it is not worth while to inquire, the term has been applied by most modern writers, particularly poets, to a creature of another class, a genuine fish, of the genus *Coryphæna*. No fault therefore can be imputed to the naturalist, if the general misapplication of the term is now found to occasion any misconception. There is no doubt, however, that the animal beloved by gods and men, the *Hieros Ichthys* of the heroic Greeks, and the revered symbol of the *Delphic* Apollo, was nothing more than a pellock or porpoise.[2]

2*d.* Genus Lampugus,[3] Cuv. Head oblong; central crest of the forehead much lower than in Coryphæna; dorsal fin equal, and low throughout its whole extent.

More than one species occurs in the Mediterranean, but the most common in that sea is *L. pelagicus*, which almost in every thing resembles the so-called dolphin, except in the form of its head, and more diminutive dimensions.

3*d.* Genus Centrolophus, Lacép. Form more lengthened; palatine teeth wanting; an interval between the occiput and the commencement of the dorsal fin.

Most of the species occur in the Mediterranean; and the *black perch* of Pennant, the *black fish* of Couch and Yarrell (*Cent. pompilus*, Cuv.), is referrible to this genus. It is a fish of great strength and velocity, measuring from two to three feet, and is one of our rare British species.

Genus Astrodermus, Bonelli. Head elevated and sharp; mouth slightly cleft; only four branchial rays; ventrals very small, and placed upon the throat; scales scattered upon the body, and assuming the radiated form of little stars. It is from the latter circumstance that the genus derives its name.

There is only a single species of this genus,—recently discovered, and still extremely rare. It has been taken near Nice, and also in the Gulf of Cagliari in Sardinia, and was originally described by M. Risso under the name of *Coryphæna elegans*.

Genus Pteraclis. Head and teeth as in *Coryphæna*, but the scales are larger, the ventrals very small, and placed upon the throat; the dorsal and anal fins prodigiously extended.

This eccentric genus is founded on a fish described by Pallas in his *Spicilegia*, under the name of *Coryphæna ve-*

---

[1] Every voyager seems to describe the dolphin in his own way; and it is by no means easy for a landsman to ascertain which is the right one. The play of colour, as it is called, may no doubt admit of great diversity in the expressions used. The above description is from the recorded observation of the living fish by M. Biberon. Another eye-witness, Colonel Bory St Vincent, describes the back as being of a sea-green colour, sprinkled with orange spots; the abdomen silvery; the lateral line yellow; the dorsal fin celestial blue, with golden-coloured rays; the caudal fin surrounded by a green hue; the other fins yellow. (*Dictionnaire Classique d'Hist. Nat.* t. iv. p. 528.)

[2] Wilson's *Illustrations of Zoology*, vol. i. article Delphinapterus.

[3] Synonymous with the genus *Caranxomus* of Lacépède, which was adopted by Cuvier in the *Règne Animal*, but is now, so far as the name is concerned, handed over to oblivion.

Acanthopterygii. Scomberidæ.

lifera, and it was with a feeling of doubt that Cuvier placed it where it now stands. It is not easy to conceive the use of its dorsal and anal fins, so enormously large in proportion to the size of the body. Pallas indeed imagined that they might serve to sustain it in the air; but in that case the fish must fly, as a flounder swims, upon its side. The species are unfortunately so rare, that it may be long before an opportunity occurs of throwing any light upon the subject. The only known specimen of *Pt. ocellatus*, Cuv. was taken entire from the stomach of a bonito in the Straits of Mosambique. The species represented in this work (See Plate CCCIII. fig 3) was brought to Europe by MM. Quoy and Gaymard, but we know not from what locality.

Genus Stromateus, Linn. Distinguished among the Scomberidæ by the want of the ventral fins, and by a single dorsal, the spiny rays of which, few in number, are concealed in its anterior margin. The vertical fins are covered by scales, as among the Squammipennes.

The Mediterranean produces a beautiful species (*St. fiatola*, Linn.), remarkable for its spots and broken bands of gold upon a lead-coloured ground. The *black pomfret* of India, a delicious fish for table uses, pertains to this genus. It is the *St. niger* of Bloch. According to Russel, it is abundant at Vizagapatam during the months of March and April, and vanishes and re-appears alternately every two or three days. It requires to be eaten immediately after capture.[1] A singular circumstance in the geographical history of this genus is, that although the species seem common along a great extent of Indian coast, and spread as far as China, none is known at the Isle of France, nor in any part of the Indian Archipelago.

Genus Rhombus,[1] Lacép. Extremity of the pelvis forming, anterior to the anus, a small pointed and cutting blade, which resembles a vestige of the ventral fins.

As an example, we may mention the *Harvest fish* of New York, an excellent article for the table. It is the *Rh. longipinnis* of Cuvier, erroneously placed by Linnæus among the Chætodons.

The genus Luvarus of Rafinesque resembles the preceding. There is only one species distinctly known (*L. imperialis*), a fish of fine flavour, but extremely rare. It measures five feet in length; the whole body is of a reddish silvery colour, more obscure upon the back. It was dashed ashore near Solanto, in Sicily.[2] A species unknown to the fishermen was taken in 1826, at Isle-de-Ré, which Cuvier regards as referrible to this genus. The genus Seserinus, Cuv. possesses the characters of Stromateus, but very small ventrals are perceptible, or at least the vestiges of these organs are apparent. The only known species is *S. Rondeletii*, a small fish of the Mediterranean.

Genus Kurtus, Bloch. Allied to Rhombus, but differs in the dorsal fin being shorter, and the ventrals more developed. The scales are so fine as to be imperceptible in the dried state. There are seven branchial rays. The pelvis shows a spine between the ventrals, and several small cutting blades are visible anterior to the dorsal fin, at the base of which is a spine directed horizontally forwards.

The skeleton in this genus presents a striking peculiarity in the ribs, which are dilated, convex, and in the form of rings which come in contact with each other,—thus enclosing a conical empty space, which is prolonged beneath the tail, in the inferior rings of the vertebræ, into a long thin tube enclosing the swimming bladder. The species inhabit the Indian seas, and are few in number. *K. cornutus*, called *somdrum-hara-moddee* at Vizagapatam, and which Cuvier regards as the male of *K. Blochii*, Lacépède, is an excellent eating fish, remarkable for being almost transparent in a state of freshness.

We shall conclude our exposition of the Scomberidæ by a brief notice of the genus Zeus, Linn. from which some of the preceding genera, such as *Gallychtis*, *Argyreyosus*, &c. have already been detached. In its more restricted form it contains fishes of a compressed body, protractile mouth covered by small scales, with teeth feeble and few in number. It is further divisible as follows:

Genus Zeus, Cuv. Dorsal fin emarginate, its spines accompanied by long slips of the membrane; a series of forked spines along the base of the dorsal and anal fins.

The type of the genus is *Zeus faber*, commonly called the *Dory* (Plate CCCIII. fig. 5), probably from the French term *dorée*, in allusion to the golden tints of its body.[3] Its surface has at the same time a smoked appearance, on which account the French name it *forgeron*, a word which corresponds to the Latin trivial name of *faber*, or blacksmith. It is also called the *fish of St Peter*, from an ancient traditionary belief that it was from the mouth of this species that the apostle extracted the tribute-money, and the black spot on either side of its body is supposed to be a record of its capture at that time.[4] The dory is a fish greatly esteemed for the table. It occurs both in the Mediterranean Sea, and along the oceanic coasts of Europe. According to Pennant, the largest are found in the Bay of Biscay. Willughby alludes to it as common in his day on the shores of Cornwall; and it is still taken both there and along the Devonshire coast, occasionally even in profusion. Mr Couch, as quoted by Mr Yarrell, considers the dory rather as a wandering than a migratory fish, and as regulated in a great measure by the movements of the smaller kinds on which it preys. When the pilchards approach the shore, it is frequently taken in considerable numbers. In the autumn of 1829, more than sixty were hauled on shore at once in a net, some of them of large size, and yet the whole were sold together for nine shillings. The largest specimens of the London market weigh from ten to twelve pounds, but the average weight is scarcely more than five. The dory is a bold, voracious species, preying greedily upon the more timid kinds, and pouncing readily upon all sorts of bait. Its flesh was highly esteemed in the time of Pliny. Columella, who was a native of Cadiz (where it was regarded as the best of fishes), has recorded that it had been long known by the name of *Zeus*—a designation which in

---

[1] In the second edition of the *Règne Animal*, this genus bears the name of Peprilus; Cuvier not having been at that time aware that it had been previously designated by Lacépède under the name of *Rhombus*. We deem the choice of the latter name equally unfortunate, seeing that it had been previously applied generically to that group of the Pleuronectidæ called *Turbots*. But we leave it to more influential authors to propose a second change.

[2] Rafinesque, *Caratteri di alcuni nuovi generi*, &c. *della Sicilia*, p. 22.

[3] A variety of derivations, however, have been assigned to the English name. In addition to the one above alluded to, we shall merely mention the following: St Christopher, while wading through an arm of the sea, and bearing the infant Saviour, is said to have caught a dory, and to have impressed its sides with the two peculiar marks, as a perpetual record of the fact. The name was therefore said to be from the French *adorée*, worshipped, as something unusually sacred. The designation of *John Dory* is in all probability derived from the French *jaune dorée*, in allusion to the tints of a *golden yellow* hue with which it is adorned. Some, however, refer it (and again in connection with St Peter) to the Italian term *janitore*, or door-keeper, by which it seems the species is known to the fishermen of the Adriatic.

[4] The common haddock also bears a share in this tradition.

itself argues pre-eminence, Ζευς in Greek signifying the monarch of the gods.

Genus Capros, Lacép. Dorsal fin emarginate, as in the preceding, and the mouth still more protractile; but there are no spines to either the anal or dorsal fin. The body is covered with strong rough scales.

The only species with which we are acquainted is the *Zeus aper* of Linn. a small fish of the Mediterranean. A specimen was taken in Mounts Bay in October 1825,[1] and more recently it was observed in the Bridgewater fish-market, as we are informed by W. C. Trevelyan, Esq.

Genus Lampris, Retzius. A single dorsal fin, high in front, where it is furnished with one or two small spines. The ventrals have ten long rays, and the lobes of the caudal fin are considerably elongated, but these prolongations seem to become effaced by age. The sides of the tail are carinated.

The only known species (*L. guttatus, Zeus luna*, Gmelin) occurs, though rarely, off the French coasts, and in the British seas, where it is known as the *opah* or king-fish. It is one of the most splendid and remarkable of European fishes. Its back is of a deep blue spotted with silver,—the rest of its body like polished gold, reflecting all the colours of the rainbow. It is certainly sufficiently singular that a species included by Nilsson in his *Prodromus* of the fishes of Scandinavia, should likewise be enumerated by Kæmpfer as occurring in Japan. The opah is a fish of great size, measuring sometimes five feet in length. Its flesh is said to taste like beef. See Plate CCCIII. fig. 6.

The remaining genera are Equula, Cuvier, and Mene, Lacépède. The *Zeus insidiator* is an example of the former,—the *Zeus maculatus*, of the latter.

FAMILY VIII.—TÆNIOIDÆ.

This family is closely connected with the Scomberidæ. The species are of a very lengthened form, and flattened laterally, from which they have obtained the name of ribbon-fishes. Their scales are very small.

The first tribe[2] comprehends those genera of which the mouth is small, and but slightly cleft.

Genus Gymnetrus, Bloch. Body elongated and flat; anal fin entirely wanting; dorsal fin long, with prolonged anterior rays, which, however, are easily broken; ventrals also very long, when not worn away by use, or otherwise fractured; the caudal, composed of few rays, rises vertically on the extremity of the tail, which finishes in a little hook. There are six branchial rays.

The species are so soft and tender that they often present themselves as it were with false characters, from the natural mutilation of the rays. For this reason they are as yet indistinctly characterized by systematic writers. Even the central skeleton, and especially the bones of the vertebræ, are extremely soft. The stomach is long; there are numerous cæca; the swimming bladder is wanting; and the flesh, of a mucous nature, decomposes with great rapidity. The European species occur in the Mediterranean, and also occasionally in the British and more northern seas. The fish called *king of the herrings* by the Norwegians belongs to this genus. We here figure as a curious example the *Gymnetrus falx*. See Plate CCCIII. fig. 8. We may add, that the *Gymnetrus Hawkenii* of Bloch, a species originally described from a specimen taken near Goa, in the Indian Sea, was many years ago drawn ashore dead on the south coast of Cornwall. It measured nearly nine feet, and weighed forty pounds. The *vaagmaer*, or *deal-fish*, has also been recorded by Dr Fleming as a British species.[3] It is the *Gymnetrus Arcticus* of systematic authors.

That very singularly-formed fish, the *Stylephorus cordatus* of Shaw, forms the remaining genus of the present tribe.[4]

In the second tribe of Tænioidæ the muzzle is short, and the mouth obliquely cleft.

Genus Cepola, Linn. Dorsal and anal fin long, each reaching to the base of the caudal, which itself is rather large; the cranium is not raised or crested; the muzzle is very short, with the superior curved upwards; the teeth are distinct, and the ventral fins perceptibly developed. There are a few unarticulated rays in the dorsal fin, which are as flexible as the others; the spine of the ventrals alone being stiff and pointed. There are six branchial rays. Both the abdominal cavity and stomach are very short. Some cæca are perceptible, and a swimming bladder, which extends into the caudal extremity. The occasional occurrence of a Mediterranean species of this genus (*Cep. rubescens*, Linn.) along the coasts of Devon and Cornwall has been recorded both by Montagu and Couch.[5]

Genus Lophotes, Giorna. Head short, surmounted by a raised osseous crest, on the summit of which is articulated a long and powerful spiny ray, bordered behind by a membrane, and followed by a low simply rayed continuous fin, which spreads onwards to the point of the tail. Caudal fin distinct but small; and beneath the abovementioned point there are two scarcely perceptible ventral fins furnished with four or five exceedingly small rays. The teeth are pointed, and not very close together; the mouth directed upwards, and the eyes very large. There are six branchial rays, and the abdominal cavity occupies almost the entire extent of the body. We are acquainted with only a single species (*Loph. Lacepedianus*), which inhabits the Mediterranean, where, however, it is extremely rare. It attains to a large size, that is, to about four feet in length.[6]

FAMILY IX.—THEUTIDÆ.

This family is perhaps as closely allied to the Scomberidæ as the preceding, but its alliance proceeds from other points,—such as the armature of the sides of the tail in several genera, or the horizontal spine anterior to the dorsal fin in others. It comprises but a small number of foreign genera, with compressed oblong bodies, small mouths, slightly or not at all protractile, armed on each jaw with cutting teeth upon a single range, the palate and tongue without teeth, and a single dorsal fin. The species are of herbivorous habits, feeding chiefly on fuci and other marine vegetation. Their intestines are ample. We are compelled to be brief in our indications of the generic groups.

The genus Siganus, Forsk. of which the species are

---

[1] *Proceedings of the Zoological Society*, 1833, p. 113.

[2] In the *Règne Animal*, t. ii. p. 217, the first tribe of the family above named is composed of the genera *Lepidopus* and *Trichiurus*, which, however, in Cuvier's later work (*Hist. Nat. des Poissons*, t. viii. p. 217) are placed as an appendix to the first tribe of the Scomberidæ, where we have accordingly placed them in the present article. We therefore commence the Tænioidæ with what was formerly the second tribe.

numerous in the Indian seas, is characterized by a feature believed to be unique among fishes, that of having both the outer and inner ray of the ventral fins spiny. The genus ACANTHURUS, Bloch, has the teeth cutting and dentated, and a strong moveable spine on each side of the tail, capable of inflicting a severe wound on those who grasp it incautiously. On this account a species greatly sought for in the West Indies as food has received the name of surgeon, *Ac. Chirurgus.* As an example we here figure the *Acanthurus Delisianus.* See Plate CCCIII. fig. 7. In the genus NASEUS the sides of the tail are armed with fixed spines, and the teeth are conical. The great peculiarity, however, consists in a horn-like prominence on the front of the head. The skin resembles leather. Forskall relates of one species (*N. fronticornis,* Lac.) that although of peaceable demeanour and herbivorous habits, it knows how to defend itself from unprovoked aggression; and he reports the observations of some Arabian fishermen, who saw a troop of them come to the rescue of a companion who had been transfixed on the surface of the water by an eagle. They so bothered the "Bird of Jove" as eventually to produce his death by drowning. This, however, savours more of an "Arabian Tale" than of a fact in natural history. See Plate CCCIII. fig. 9. The reader will perceive in the two preceding representations a resemblance to the genus Chætodon. The remaining genera of this small family are AXINURUS and PRIODON, Cuv.

FAMILY X.—LABYRINTHIFORM PHARYNGEALS.

By this term Baron Cuvier means to designate the peculiar structure of a part of the upper pharyngeal bones, which are divided into leaflets more or less numerous and irregular. This formation produces cells capable of containing water, which flows upon and moistens the branchiæ for some time after the fish itself has been removed from its natural element; and this refreshing influence is rendered the more effectual by the closeness of the opercula or gill-covers. The consequence is, that most of the species possess the power of quitting their streams and pools, and creeping, as it were, to some little distance from their watery homes,—a faculty not unknown to ancient writers, and one which in India has led to the belief that these fishes fall from heaven.

GENUS ANABAS. In this genus the labyrinths alluded to attain the greatest degree of complication. Nevertheless the third pharyngeals have teeth *en pavés,* and there are others beneath the back of the cranium. The body is round, covered by strong scales; the head large; the muzzle short and obtuse; the mouth small; the lateral line interrupted about its posterior third. The margins of the opercle, sub-opercle, and inter-opercle, are strongly toothed, but not those of the pre-opercle. The branchial membrane has five rays. There are many spiny rays to the dorsal, and even to the anal fin. The stomach is of medium size, rounded. The pylorus has only three appendices.

The generic name is derived from the Greek, *αναβαινω, to ascend,* and refers to the singular instinct of the only known species (*An. scandens,* Plate CCCIII. fig. 11), which induces it to climb trees.[1] It performs this action by means of the spiny processes of the gill-covers, and moves at pleasure up the trunks of trees which grow by the water side. It was observed by Lieutenant Daldorff, at Tranquebar, ascending by a fissure in the stem of the palm called *Borassus flabellifer,* and was also found to be so tenacious of life as to move about upon the dry sand for some hours after it was captured on the tree.[2] At the same time other respectable observers who have attended to this species in its natural state, make no mention of the fact. M. Reinwardt has frequently taken the Anabas at Java, but never heard any climbing propensities attributed to it; M. Leschenault, who transmitted several specimens to Pondicherry, simply observes that they dwell in rivers and fresh-water ponds; while Mr Hamilton Buchanan proceeds still further, and not only denies the fact, but regards it as contrary to the laws of nature. One point, however, is certain, that it is capable of living an unusual length of time out of the water, a fact in perfect accordance with the peculiar structure of its pharyngeals. It also creeps about upon the ground for hours together, and the fishermen are alleged to keep it alive for five or six days in a dry vessel. It is thus brought alive to the markets of Calcutta from the great marshes of the district of Yazor, which are distant more than a hundred and fifty miles. "Les charlatans et jongleurs," says Cuvier, "dont l'Inde abonde, ont généralement de ces poissons avec eux dans des vases, pour amuser la populace de leurs mouvemens."[3]

Passing over the nearly allied genera of HELOSTOMA, POLYACANTHUS, COLISA, and MACROPODUS, we arrive at the

GENUS OSPHRONEMUS of Commerson, of which the forehead is somewhat concave, the anal fin larger than the dorsal, the sub-orbitals and base of the pre-opercle finely dentated, and the first soft ray of the ventrals remarkably prolonged. There are six branchial rays, and the general form of the body is much compressed.

This genus contains the *Os. olfax,* or *Gourami,* one of the most famous for its flavour of all the fishes of the East. See Plate CCCIII. fig. 10.) It grows as large as a turbot, and is even more delicious than that favourite food. Commerson has recorded in his manuscript that he never tasted so exquisite a fish,—"Nihil inter pisces tum marinos tum fluviatiles exquisitius unquam degustavi;" and he adds, that the Dutch of Batavia rear them in large earthen vessels, renewing the water every day, and feeding them on aquatic plants, particularly *Pistia natans.* That navigator was also of opinion that the species had been imported originally from China to the Isle of France, and it appears to have been recently conveyed to the French colonies in South America by Captain Philibert. Its importation to Europe would be well worth attempting, and would probably be attended by success if the Gourami, like the golden carp, is actually a native of China. It does not, however, appear that any mention is made of it in any natural history notices of that empire, and it seems as yet unknown in India. It is said that the female Gourami hollows out a little foss in the side of the pond where she is kept, for the purpose of depositing her eggs in safety.

The remaining genera of this group are TRICHOPUS, SPIROBRANCHUS, and OPHICEPHALUS. Of the former two only a single species is known of each. The last named is more numerous, and is deserving of a brief notice.

The *Ophicephali* resemble all the preceding genera of the family in the majority of their characters, and particularly in the cellular disposition of their pharyngeals, which seem equally adapted for the singular retention of water before alluded to. They can consequently also creep to a considerable distance from their liquid abodes; but what particularly distinguishes and even separates them from all

[1] It is synonymous with *Perca scandens* of Daldorf, and *Coius coboius* of Buchanan. In the Tamoul language it is called *Panciri,* or the *tree climber.*

[2] *Linn. Trans.* vol. iii. p. 62.

[3] *Hist. Nat. des Poissons,* t. vii. p. 332.

other acanthopterygian fishes, is the absence of spines to the fins, except the single one to the ventrals, which itself, though simple, is neither stiff nor pointed. The body is elongated, and almost cylindrical; the muzzle short and obtuse; the head depressed, and furnished with polygonal scales, or rather plates, as in *Anabas*. It may be said, however, that it is by means of the solitary ventral spines alone that they exhibit the normal character of the great division of acanthopterygian fishes with which we have been hitherto engaged. They thus, by such ambiguous combination of character, almost break up the grand distinction of acanthopterygian and malacopterygian species, a distinction otherwise so well grounded as to have hitherto produced no disruption of the relations of natural affinity. "If it were possible," says Cuvier, "to admit that anomalous beings existed in nature, there is certainly none to which the title is so justly due as to the Ophicephali." Their watery reservoirs enable them to journey from one marsh to another, and they are moreover so tenacious of life that their bowels may be torn out, and themselves cut to pieces, without producing immediate death. They are often thus carried about alive, or sold in the markets slice by slice; and the consumers refuse to give the best price when so much has been cut away that the remainder ceases to move. This seems a parallel case to that of the beef-steaks from the oxen of Abyssinia. We here figure as an example of this singular genus the *Ophicephalus striatus*, a species which seems spread over the whole of India. See Plate CCIII. fig. 12. Buchanan describes another species under the name of *Gachua* (*Oph. marginatus*, Cuv.?), which sometimes grows to a foot in length. It is very common in the ponds and fosses of Bengal, and is one of the species most generally believed to fall from the clouds in wet weather. During the first heavy showers of the rainy season, they are certainly seen crawling on the grass; but their object in so doing is doubtless to escape from the corrupted water of the narrow dykes which they had previously inhabited, and to go in search of a purer element, and a fresher and more ample food. The species called *Barca* by Buchanan lives in holes in the vertical banks of the Brahmapootra, with nothing visible but its head, that it may the more readily observe and seize its prey. It is a large fish, measuring three feet in length, and is regarded as good eating. On the whole, however, the species of this genus are consumed rather by natives than Europeans,—the latter probably regarding them too much in the light of reptiles. We may add, that the *Ophicephali* are often exhibited by the Indian jugglers, and that even the children amuse themselves by forcing them to crawl upon the ground.

FAMILY XI.—MUGILIDÆ.

The fishes which compose our present group (corresponding to the genus Mugil of Linn.) exhibit so many peculiarities of organization, that Cuvier has deemed it advisable to form them into a distinct family. The body is almost cylindrical, covered with large scales, and furnished with two distinct dorsal fins, the first of which has only four spiny rays. The ventrals are attached somewhat behind the pectorals. The gills have six rays. The head is rather depressed, also covered with large scales or polygonal plates. The muzzle is very short. The transverse mouth forms an angle by means of a prominence of the middle of the lower jaw, corresponding to a depression of the upper one; and the teeth are excessively fine, indeed in some cases imperceptible. The pharyngeal bones, greatly developed, give an angular form to the œsophagus resembling that of the mouth, which permits only fluids or very small substances to enter the stomach, notwithstanding which the latter terminates in a kind of fleshy gizzard, analogous to that of birds. The pyloric appendices are few in number, but the intestine is long and folded.

Acanthopterygii. Mugilidæ.

The species are excellent as articles of food. They resort in vast troops to the mouths of large rivers, where they may be observed continually springing out of the water.

The *Mugil cephalus*, or Mediterranean gray mullet (the English name must not mislead the unpractised reader to confound it with the genus *Mullus*, formerly described), is distinguished from all the other European species by its eyes, which are half covered by two adipose veils adherent to the anterior and posterior margin of the orbit, and by the peculiar concealment of the maxillary bone, which, when the mouth is closed, is completely hidden beneath the sub-orbital. The base of the pectoral fin is surmounted by a long carinated scale. See Plate CCCIII. fig. 13. The species just referred to is the best and largest of the Mediterranean kinds. It weighs about ten or twelve pounds, and does not appear to have been yet detected in the seas or estuaries of Britain, nor along the oceanic shores of France. It is very common on the coast of Spain, especially around the island of Ivica, where the fishermen are said to recognise two varieties under the names of *Mugil* and *Lissa*. When surrounded by a net, it endeavours, and often successfully, to effect its escape, by leaping over the edges into the unencumbered sea.[1]

"Its hearing is very fine, as has been noticed by Aristotle, and it feeds on worms and small marine animals; but it is doubtful, though it has been advanced, that it can live on vegetable substances. It appears to be of a stupid character, a fact which was known in the time of Pliny, for that author tells us that there is something ludicrous in the disposition of the mullets; for if they are afraid they conceal their heads, and thus imagine they are entirely withdrawn from the observation of their enemies.

"When, towards the end of spring and the commencement of summer, the fishes of this species, excited by the necessity of living in the fresh water, approach the shores and advance towards the mouths of the rivers, they form such numerous troops that the water through which they are seen, without being clearly distinguished, appears to be bluish. This particularly happens in the Garonne and the Loire at these periods. The fishermen there adopt the plan of surrounding these legions of mullets with nets, the enclosure of which they gradually contract, taking care to make a noise to frighten the fish, and oblige them to press together, and heap themselves as it were one upon the other.

"Of the mullets thus taken some are eaten fresh, others are salted and smoke-dried; it is with their eggs salted, washed, pressed, and dried, that the preparation called *botarcha* is made, which is a condiment greatly in request in Italy and the southern provinces of France. The flesh of this mullet is tender, delicate, and of an agreeable flavour; it is fatter and more in estimation when it is taken in the fresh water. The ancients, who from the time of Aristotle were acquainted with this fish, had it in great request; and the consumption of it is still very considerable in most of the southern countries of Europe. According to the report of Athenæus, those mullets were formerly in very high esteem which were taken in the neighbourhood of Sinope and Abdera; while, as Paulus Jovius informs us, those were very little prized which had lived in the salt marsh of Or-

[1] The *Mugil saliens* derives its specific name from the extraordinary velocity with which it springs into the air when it finds itself about to be enclosed.

bitello in Tuscany, in the lagunes of Ferrara and Venice, in those of Padua and Chiozza, and such as came from the neighbourhood of Commachio and Ravenna. All these places in fact are marshy, and the streams by which they are watered are brackish, and communicate to the fish which they support the odour and the flavour of the mud."[1]

At the conclusion of this family Cuvier places the two following genera, the first of which is allied partly to the mullets and partly to the Scomberidæ, while the second partakes of characters intermediate between the Mugilidæ in general, and the ensuing family of Gobioidæ.

Genus Tetragonurus, Risso, so called from two salient crests on each side, near the base of the caudal fin. The body is elongated; the spinous dorsal long, but very low,—the soft dorsal approximate, but higher and short, with an anal of corresponding form; the ventrals are a little behind the pectorals; the branches of the lower jaw are vertically raised, and furnished with a range of pointed cutting teeth, forming as it were a saw, and fitting, when the mouth is closed, into those of the upper jaw. The stomach is garnished interiorly with hard and pointed papillæ.

The only known species (*T. Cuvieri*, Risso) is found along the Mediterranean shores, but only at great depths. It is of a black colour, measuring about a foot in length, and is covered by hard, toothed, striated scales. Its flesh is said to be poisonous.

Genus Atherina, Linn. Body elongated; dorsals wide apart; ventrals further back than the pectorals; mouth very projectile, and furnished with extremely small teeth. The transverse processes of the last abdominal vertebræ are bent so as to form a little conical bag for the reception of the point of the swimming bladder.

All the known species are characterised by a broad silvery band along the sides. They are highly esteemed for their delicacy; and the fry, which continue for a long time together in crowded troops, are eaten along the Mediterranean shores under the name of *Nonnat*. *A. hepsetus*, Linn. was till very recently regarded as indigenous to the seas and estuaries of Britain. There was reason, however, to believe that several species had been confounded under that name; and Mr Yarrell has ascertained that the British species, commonly called the Atherine, coincides in its characters with the *Atherina presbyter* of Cuvier. It is a common fish at Brighton, where, under the name of *sand-smelt*, it is eaten in large quantities by the inhabitants and visitors during the winter months. It partakes of the cucumber smell and flavour of the true smelt, and is a small handsome fish, measuring from five to six inches. It is rarely brought to the London market. It spawns in May and June.

FAMILY XII.—GOBIOIDÆ.

This family derives its name from the Linnæan genus *Gobius*, and is distinguished by having the dorsal spines slender and flexible. The viscera of all the fishes pertaining to it are nearly of the same conformation; the intestinal canal is equal, ample, and without cæca, and there is no swimming bladder.

The species referrible to the genus *Blennius*, Linn. present a very distinctive character in having their ventral fins placed before the pectorals, and composed only of two rays. Their bodies are elongated and compressed, and they bear only a single dorsal, composed almost entirely of simple and flexible rays. They live in small companies in rocky streams, and can survive for a considerable time out of the water, in consequence of their skin being covered with a kind of mucus, a circumstance which has caused the Greek name *Blennius* to be applied to them. Many of them are viviparous, and both sexes have a tubercle near the anus, which seems to be subservient to the purposes of copulation. They are now arranged under the following genera:

Genus Blennius, Cuv. Includes the blennies properly so called, and is characterised by long, equal, and closely-placed teeth, forming only a single and rather regular row on each jaw, terminating behind in some species by a long and hooked tooth. The head is obtuse, the muzzle short, and the forehead vertical; the intestines broad and short. Several species occur along the coasts of Britain. Of these we may mention the butterfly blenny (*B. ocellaris*), distinguished by having the dorsal bi-lobed, the anterior lobe being very elevated, and marked with a round black spot, cinctured with a white and black circle. See Plate CCCIV. fig. 1.

Genus Myxodes, Cuv. Separated from the blennies properly so called, in consequence of the head being elongated, the snout pointed, and projecting beyond the mouth; the range of teeth like those of the blennies, but without the canine teeth.

Genus Salarias, Cuv. Teeth laterally compressed, hooked at the extremity, exceedingly slender, and in prodigious numbers. The head of these fishes is very much compressed superiorly, and of great breadth across the base: their lips are fleshy and thick, their forehead quite vertical, and their intestines, spirally convoluted, are longer and more slender than in the common blennies. All the known species are from the Indian Ocean.

Genus Clinus, Cuv. Teeth short and pointed, disposed in several rows, the first of which is largest. Their muzzle is less obtuse than in the two preceding groups, the stomach broader, and the intestines not so long.

Genus Cirrhibarbus, Cuv. The general form is that of the preceding genus; the teeth are crowded, and there is a small tentaculum over the eye, and another on the nostril, besides three large ones at the extremity of the muzzle, and eight under the point of the lower jaw. Only one species is known, a native of the Indus. It is of a uniform reddish-yellow colour.

Genus Gunellus. (*Murænoides*, Lacép.) Distinguished from all the other blennies by having the ventrals so

---

[1] Griffith's edition of the *Animal Kingdom*, vol. x. p. 300. According to Baron Cuvier, Linnæus and several of his successors have confounded all the European mugils or gray mullets under the single specific name of *M. cephalus*. The French naturalist restricts that denomination to the species characterised above, and which has not yet been detected along our island shores. Our *gray mullet* is the *mugil capito* of Cuvier, an inhabitant not only of the Mediterranean, but also of all the western shores of the temperate parts of Europe. "The partiality," says Mr Yarrell, "exhibited by the gray mullet for fresh water has led to actual experiment of the effect of confining them to it entirely. Mr Arnould put a number of the fry of the gray mullet about the size of a finger into his pond at Guernsey, which is of about three acres area, and has been before referred to under the article *Basse*. After a few years, mullet of four pounds weight were caught, which proved to be fatter, deeper, and heavier for their length, than others obtained from the sea. Of all the various salt-water fishes introduced, the gray mullet appeared to be the most improved. A slight change in the external colour is said to be visible." (*British Fishes*, p. 205.) The same author informs us that the gray mullet is frequently an object of sport to the angler. They rise freely at the flies used for trout, and even at the larger and more gaudy flies used for salmon. They are strong in the water, and require a careful hand in consequence of their impetuous plunging. Our other British species are the thick-lipped gray mullet, *mugil chelo*, Cuv., and a small species described by Mr Yarrell under the name of short gray mullet, *mugil curtus*. We may here remark, that it is unfortunate that the English term *mullet* should be applied both to the subjects of our present note, and to the red and striped mullets, which belong to a very different genus of the family Percidæ, before described. If the latter were termed *surmullets*, or the former *mugils*, the ambiguity of a double application of the same name would be avoided.

small as to be almost imperceptible, and often reduced to a single ray. The head is very small, and the body elongated like the blade of a sword; the back garnished throughout its whole length with a uniform dorsal fin, all the rays of which are simple and without articulations. The teeth are as in the genus *Clinus*, the stomach and intestines of a uniform character.

One species, the common gunnel (*B. gunnellus*), is very abundant on the coasts of Britain, and in other northern seas. It varies from six to ten inches in length, is of a yellowish-brown colour on the body, with the belly white, and the dorsal fin ornamented with a series of dark ocillated spots along the base.

Genus Opistognathus, Cuv. Presents the form of the blennies properly so called, but differs from them in having the maxillaries very large, and prolonged posteriorly into a kind of long flat moustache. The teeth in each jaw are rasp-like, the exterior range being strongest. The ventrals are placed exactly under the pectorals, and consist of three rays. Only one species seems to be known, which was brought from the Indian Ocean by M. Sonnerat, after whom it was named by Baron Cuvier.

Genus Zoarcus, Cuv. The species of this group are destitute of a spiny ray; they have an anal tubercle, the intestines are without cæca, and there are six branchial rays. The ventrals have three rays; the teeth are conic, and placed in a single row along the sides of the jaws, but in several in front; the palate is without teeth. Their dorsal, anal, and caudal fins are united, although the first named experiences a great depression.

The viviparous blenny (*B. viviparus*) is a well-known species, and has been long celebrated for a peculiarity which is chiefly observable among cartilaginous fishes, that, namely, of producing its young alive. These are so matured at the time of their birth, that on their first exclusion they swim about with the utmost agility. No fewer than 200 or 300 young are sometimes produced by an individual, and the abdomen of the mother is so distended before parturition, that it is impossible to touch it without causing them to be extruded. Full-grown individuals seldom exceed twelve inches in length; the body is slender and smooth; the colour yellowish olive, pale beneath, and marked on the upper parts with dusky spots. It is a littoral fish, and of frequent occurrence under stones. When boiled, the back-bone acquires a green colour. America produces a much larger species, which sometimes exceeds the length of three feet. It has been described under the name of *Blennius labrosus*.

Genus Anarrhichas, Linn. Bear so much affinity to the blennies, that the species have been termed by Cuvier Blennies without ventrals. The dorsal fin, entirely composed of simple rays, but without stiffness, begins at the nape, and extends, in common with the anal one, nearly to the caudal fin, which is rounded like the pectorals. The whole body is smooth and covered with mucus. Their palatines, vomer, and mandibles, are armed with large osseous tubercles, which are crowned with small enamelled teeth; but the anterior teeth are longer and conical. Such a conformation of the teeth makes them very powerful instruments, and these fishes, from their large size, are thereby rendered ferocious and dangerous. They have six rays in the gills; the stomach is short and fleshy, with the pylorus near its base; the intestine short, thick, and without cæca; and the swimming bladder is wanting.

The most common species is the *A. lupus*. Plate CCCIV. fig. 2. It is of frequent occurrence in most of the northern seas, and is well known along the coasts of Britain by the names of *sea-wolf* and *sea-cat*. Its ordinary length is from three to four feet, but examples sometimes occur nearly double that size. The colour is obscure livid brown, with several transverse stripes or bands of a darker hue. The dorsal fin, as already mentioned, extends along the whole length of the back, and is composed of seventy-three rays. The fore teeth project considerably, and diverge a little from each other, forming a powerful kind of armature, moved by jaws of such strength that the animal has been known to imprint the marks of its teeth on a bar of iron. The uninviting aspect of this fish has probably not been without influence in producing a prejudice against it as an article of food. Its flesh, however, is far from being unsavoury, and bears considerable resemblance to that of the eel. It is in great request among the Icelanders, who eat it dry and salted; while the other parts of the fish are likewise converted to useful purposes, the skin forming shagreen, and the gall being used as soap.

The gobies (*Gobius*, Linn.) are at once distinguished from their associates by having their thoracic ventrals united, either throughout their whole length, or only towards the base, and forming a single hollow disk, more or less tunnel-shaped.

The spines of their dorsal fins are flexible; the opening of the gills, provided there are only five branchial rays, is generally very small; and, like the blennies, they can live for some time out of the water. Their stomach is without a *cul-de-sac*, and the intestinal canal has no cæca: the males have an appendage, like the blennies, behind the anus; and some species are known to produce their young alive. They are small or middle-sized fishes, and usually frequent rocky places near the margin of the waters which they inhabit. The greater number are provided with a simple air-bladder.

Genus Gobius, Cuv. Includes the *gobies* properly so called. They have their ventrals united throughout their whole length, and even anterior to their base, by a traverse, so as to form a concave disk. Their body is elongated; the head of moderate size, and rounded, the cheeks inflated; and the eyes placed near each other. The back bears two fins, the posterior one rather long. Several species occur in European seas, the characters of which have not been sufficiently examined. They frequent waters having a clay bottom, and pass the winter in excavations which they make for that purpose. In the spring they prepare a kind of nest in places which abound with Fuci, and cover it with the roots of the Zostera: the male remains there waiting the arrival of the females, which come in succession to deposit their eggs. These he fecundates, and afterwards watches and defends courageously.

The black goby (*Gobius niger*, Linn.) is not a scarce species on the coasts of Britain. It is about five inches long, of a dark-brown colour above, and white beneath, variegated with darker spots and stripes. The tail is rounded, and the superior rays of the pectorals are free at the extremity. Several others are found in the Mediterranean, such as *G. jozzo*, *G. capito*, and *G. cruentatus*. A few are inhabitants of fresh waters, such as the small dark-coloured species described by Bonelli under the name of *G. fluviatilis*. Among foreign kinds the most remarkable are the *Cottus macrocephalus* of Pallas, in which the head is unusually large; and the *G. lanceolatus* of Bloch, distinguished by its elongated form, and pointed caudal fin.

The genus named Gobioides by Lacépède differs from the gobies only in having their dorsals united so as to form a single fin, and in the body being more elongated. The Tenioides of the same distinguished Ichthyologist have likewise a continuous dorsal line, and the body is still more lengthened. These fishes present a very peculiar aspect, in consequence of having their upper jaw very short, and the lower one high and convex, rising above it, both of them being armed with long crooked teeth, while the eye is reduced to a mere point, and entirely concealed under the skin. The cavity of the mouth is filled with a fleshy tongue almost of a globular shape, and the lower jaw has a few barbels beneath. The *Tænioides Hermanii* is the only species known: it is a native of the East Indies, and is usually found in the mud of stagnant waters.

GENUS PERIOPHTHALMUS, Schn. Contains such as have the head entirely scaly, the eyes placed quite close to each other, and furnished on their lower margin with an eye-lid capable of covering them; the pectoral fins clothed with scales for more than half their length, which makes them look as if supported by a kind of arm. Their gills being still narrower than those of the other gobies, they can live for a longer period out of the water; and in the Moluccas, their native country, they are often observed to leap out on the mud in order to escape their enemies, or to seize the small shrimps, which form their principal nourishment. In some the ventrals have a concave disk like the gobies properly so called; while in others these fins are separated almost to the base. Plate CCCIV. fig. 3.

GENUS ELEOTRIS, Cuv. In common with the gobies, the fishes referred to this genus have the first dorsal with flexible spines, and an appendage behind the anus; but the ventrals are perfectly distinct, the head obtuse and a little depressed, the eyes remote from each other, and the branchial membrane with six rays. The lateral line is faintly marked, and the viscera resemble those of the *Gobii*. The greater proportion of the species live in fresh water, and often in the mud. That named *E. dormitatrix* is a native of the Antilles; it is of considerable size, with the head depressed, the cheeks dilated, and the fins spotted with black. Others occur in Senegal and the Indies, and a small gilded species, marked with a black spot at the base of the pectoral (the *Gobius auratus* of Riss.), inhabits the coasts of the Mediterranean.

GENUS CALLIONYMUS, Linn. Possesses very strongly marked characters in the gills being open only by a hole on each side of the nape, and in the ventral fins being placed under the throat, remote, and larger than the pectorals. The head is oblong and depressed, the eyes approximating when seen from above, the inter-maxillaries very protractile, and the pre-opercles elongated behind and terminating in a few spines. The teeth are crowded, and are wanting on the palate. They are beautiful fishes, with a smooth skin, and having the anterior dorsal supported by some setaceous rays, occasionally much elevated. The second dorsal is elongated, as well as the anal. The same appendage is observable behind the anus as in the preceding genera. The stomach is not in the form of a *cul-de-sac*, and they are without cæca and air-bladder. Of this handsome genus we may mention as an example the gemmeous dragonet (*C. lyra*), which occurs not unfrequently in the British seas. Plate CCCIV. fig. 4. It derives its specific name from the form of the dorsal fin, which has been thought to bear an obscure resemblance to a lyre. The full-grown fish is about a foot in length. It is of a beautiful orange or yellow colour, spotted and striped with violet; the pupils of the eyes fine deep blue, and the pectoral fins light brown. The sordid dragonet (*C. dracunculus*) differs from the above only in having the dorsal fin short and without a fillet: by many it is conjectured to be the female of *C. lyra*. Several species inhabit the Mediterranean, such as *C. lacerta, cithara, jaculus;* and not a few are found in foreign countries.

GENUS TRICHONOTUS, Schn. Differs from the typical *Callionymi* only in having the body very much elongated, and the continuous dorsal and anal of proportionate extent. The genus COMEPHORA of Lacépède comprehends but one species, from the Lake Baïkal, which is usually found dead after storms, and is of so soft and fat a substance as to afford a considerable quantity of oil. It is distinguished from all the other members of this group by being destitute of ventrals. The genus PLATYPTERON is constituted by a few Indian fishes, which, to the large and remote ventrals of the *Callionymi*, unite a short depressed head, a small mouth, open branchiæ, and large scales: their two dorsals are short and remote.

GENUS CHIRUS, Steller (*Labrax*, Pallas). Placed by Cuvier at the end of this family, presents so many distinctive characters, that it may not improperly be regarded as the type of a new family group. The body is elongated, and garnished with ciliated scales; the head small and unarmed; the mouth but slightly cleft, and furnished with small unequal conical teeth; the spines of the dorsal are almost invariably slender, and that fin extends along the whole back. But their most distinctive feature consists of numerous series of pores, resembling several lateral lines. Their intestines are without cæcal appendages; they have often a tuft on the eye-brow, like certain kinds of blenny; but their ventrals are composed of five soft rays, as is usual in the allied species. All the known kinds, amounting to six or seven in number, are from the sea of Kamschatka, and were first described by Pallas in the 11th volume of the Memoirs of the Academy of Petersburg for 1810.

FAMILY XIII.—PECTORALES PEDICULATI.

This family, in Baron Cuvier's arrangement, comprehends such acanthopterygenous species as have the carpal bone prolonged in order to form a kind of arm, which supports the pectorals. From this peculiarity they have derived their family name. Only two genera are here included, and these are closely allied to each other, although the generality of authors have placed them widely apart.

GENUS LOPHIUS, Linn. Besides the semi-cartilaginous nature of the skeleton, and the want of scales on the skin, has for its general character pectorals supported as if by two arms, each of them sustained by two bones, which have been compared to the radius and cubitus, but which in reality belong to the carpus, and are more elongated in this genus than in any other. The ventrals are placed greatly in advance of the pectorals, and the opercles and rays of the branchiæ are enveloped in the skin, while the gills open only by a single hole, pierced behind the pectorals. The species are voracious; they have a large stomach and a short intestine, and are able to live for a very long period out of the water, on account of the small opening of their gills. The kinds now included in this genus, in the restricted sense attached to it by Cuvier, have the head excessively large in proportion to the rest of the body, and at the same time broad and depressed, and spiny in many places; the opening of the mouth very wide, and armed with pointed teeth; and the lower jaw furnished with numerous barbels. There are two distinct dorsals, of which the anterior possesses some detached rays, moveable over the head, where they rest on a horizontal inter-spinal; the branchial membrane forming a very large sac opening in the axilla, and supported by six very long rays; the operculum small. It is asserted that they lie among the mud, and by putting in motion the rays of their head, attract small fishes, which, mistaking the broad and fleshy extremities of these rays for worms, thus become the prey of the Lophii. It is also said that they can seize and retain their prey by means of their large branchial sacs. Their intestine has two very short cæca towards its origin, and the swimming bladder is awanting. Of these fishes, the most remarkable is the *Lophius piscatorius* of Linnæus. Plate CCCIV. fig. 5. It is a large fish (measuring from four to five feet in length) of the European seas, with a wide mouth, depressed head, numerous teeth, and a bearded tongue. Its aspect is extremely repulsive. The *Mountsbay Angler* of Borlase,[1] and the one from Bristol,[2] are, according to Dr Fleming, only mutilated specimens of the species just alluded to.

The CHIRONECTES (*Antennarius*, Commers.) have free rays on the head, like the preceding, the first being slender, often terminating by a tuft; and the following, increased by a membrane, are sometimes greatly inflated, and at other times united into a single fin. Their body and head are compressed, and the mouth opens vertically; their gill-covers, provided with four rays, open only by a canal, and a small hole behind the pectoral; the dorsal occupies nearly all the back. The whole body is sometimes garnished with cutaneous appendages. The branchiæ are four in number; the swimming bladder is large, and the intestine of moderate size and without cæca. By filling their enormous stomach with air, after the manner of the Tetrodons, they can inflate their abdomen like a balloon. When on land, their fins assist them in creeping, which they do almost after the manner of small quadrupeds, the pectorals, from their position, performing the office of hinder legs. Moving about in this manner, they can live without entering the water for two or three days. They are found in tropical seas; and Linnæus appears to have confounded several species under the name of *Lophius histrio.*

GENUS MALTHE, Cuv. Has the head unusually large and flattened, principally by the projection of the sub-operculum: the eyes placed very far forwards; the muzzle projecting like a little horn, and the mouth situate under it, the latter being of moderate size and protractile; the gill-covers supported by six or seven rays, and open towards the back by a hole above each pectoral; the single dorsal small and soft; the body covered with osseous tubercles, and having barbels along the sides, but there are no free rays over the head. The swimming bladder and cæca are wanting.

GENUS BATRACHUS. Derives its name from a Greek word signifying a frog, to which the species are thought to bear some resemblance, in consequence of the enlargement of the head. The latter is flattened horizontally, and wider than the body; the gape wide, and both the opercle and sub-opercle spiny; the gill-covers six-rayed; the ventrals narrow, attached under the throat, and consisting only of three rays, of which the first is wide and elongated; and the pectorals supported by a short arm, formed by the prolongation of the carpal bone. The first dorsal is short, supported by three spiny rays; the second long and soft, which is also the case with the corresponding anal one. The lips are often garnished with filaments. Such as have been dissected have their stomach in the form of an oblong sac, the intestines short and without cæca. The swimming bladder is deeply furcate anteriorly. They conceal themselves in the sand, lying in ambush for their prey. The wounds made by their spines are supposed to be dangerous. The species, which vary considerably in their form and aspect, occur both in the Pacific and Atlantic Oceans.

FAMILY XIV.—LABRIDÆ.

Easily recognised by its external aspect. The body is oblong and scaly, and the single dorsal fin is supported anteriorly by spines, each of which is generally garnished with a membranous appendage. The jaws are covered by fleshy lips; the two upper pharyngeals are supported against the cranium, and the lower one is large, all the three armed with teeth, sometimes *en pavé*, at other times pointed or in the form of plates, but generally stronger than usual. The intestinal canal is entirely without cæca, or only with two very small ones; and there is a strong swimming bladder.

The genus LABRUS of Linnæus forms an extensive group of fishes, very like each other in their oblong shape, and double fleshy lips (from which circumstance they derive their name), one of which is immediately connected with the jaws, and the other with the sub-orbitals; the gills are serrated, and have five rays; the maxillary teeth conic, the middle and anterior ones being longest; the pharyngeal teeth cylindrical and blunt, disposed *en pavé*, the superior on two large plates, the inferior on a single one corresponding to the two above. The stomach is not in the form of a cul-de-sac, but is continuous with an intestine without cæca, which, after two convolutions, terminates in a large rectum. The swimming bladder is robust and simple. The species are numerous, and the colours of many of them liable to so much variation that it is difficult to distinguish them with precision.

In recent times the Linnæan genus has been subdivided as follows:

GENUS LABRUS, properly so called. Opercle and preopercle destitute both of spines and dentations; cheeks and opercle covered with scales; lateral line straight, or nearly so.

Four different kinds have been described as inhabiting the British seas, but some of these seem to be mere varieties, such, for example, as the *L. balanus* and *L. comber* of Pennant, which are probably referrible to the *Labrus maculatus* of Bloch. *L. lineatus* is likewise a British species. The ground colour is reddish, with one or more irregular clouded bands of a deeper colour along the flanks. The dorsal has from sixteen to seventeen spines, and is marked with a dark-coloured spot anteriorly.

GENUS CHEILINUS, Lacép. Differs from the *Labri* properly so called, by the lateral line being interrupted opposite the dorsal fin, and commencing again a little lower. The scales at the extremity of the tail are large, and partially envelope the base of the caudal. They are fishes of considerable beauty, and are found in the Indian seas.

The next genus of interest is that named JULIS, in which the head is entirely smooth and without scales, and the lateral line is much bent opposite the end of the dorsal. Several species occur in the Atlantic and Mediterranean, and most of them are of very beautiful colours. The most common European one (*Labrus Julis*, Linn.) is frequent in the Mediterranean, and has likewise been found on the coast of Cornwall. It is about seven inches in length, and of a beautiful violet, relieved by a bright zigzag orange band on each side.

GENUS CRENILABRUS has been separated by Cuvier from the *Lutjani* of Bloch, and associated with the *Labri*, to which all their characters, both external and internal, correspond, except the dentation of the edge of the preopercle. (See Plate CCCIV. fig. 6.) Several species are found in the northern seas, such as *Lutjanus rupestris*, Bloch, 250, of a yellow colour, with clouded vertical bands. The British species (*C. tinca*) known under the name of *old wife*, or *wrasse*, belongs to this genus, as does likewise the *gibbous wrasse* of Pennant's *British Zoology*. The Mediterranean furnishes a great number adorned with the most beautiful colours, such as the *Labr. lapina*, Forsk, which is silvery, with three broad longitudinal

[1] *Cornwall*, 266, t. 27, f. 6.

[2] *Phil. Trans.* liii. p. 170, t. 13.

bands formed by dots of vermillion; the pectorals yellow, and the ventrals blue. Many likewise occur in tropical countries, of which we may mention *Lut. verres* (Bl. 255), *Lut. notatus*, *L. virescens*, and *L. chrysops*.

To the characters of the *Crenilabri*, the genus Coricus of Cuvier joins that of a mouth nearly as protractile as in the *Epibuli*. The latter group are very remarkable for this property, being capable of extending it to a great length, and suddenly forming it into a kind of tube by a peculiar movement of the maxillaries. They practise this artifice to seize small fishes as they swim within reach of this singular instrument. Several allied genera avail themselves of the greater or less protractility of their jaws to procure their food in a similar manner.

The whole body, and the head of the *Epibuli*, are covered with large scales, the hinder row of which encroaches even on the anal and caudal fins, as likewise takes place among the *Cheilini*. The lateral line is interrupted in a similar manner, and, in common with these last-named fishes, and the *Labri*, they have two long conical teeth in front of each jaw, and behind them small blunt ones. Those of the pharynx have not been observed. The *Sparus insidiator* of Pallas is the only species hitherto discovered. It is of a reddish colour, and found in the Indian Ocean.

Genus Clepticus. Furnished with a small cylindrical muzzle, which rises suddenly like that of the *Epibuli*, but is not so long as the head, and scarcely permits the view of a few small teeth; the body is oblong, the head obtuse, the lateral line continuous, and the scales envelope the dorsal and anal fins, almost as far as the summit of the spines. The only ascertained species (*C. genizara*) is of a reddish purple colour, and inhabits the Antilles.

Genus Elops, Commers. *Gomphosis*, Lacép. Has the head entirely smooth, as in *Julis*, but the muzzle is in the form of a long and slender tube, formed by the prolongation of their inter-maxillaries and mandibularies, which the integuments bind together as far as the small opening of the mouth. Of these fishes, the *Gomphosis cæruleus*, and *G. variegatus*, Lacép., may serve as examples. They are taken in the Indian seas, and many of them are said to form a delicious article of food. The preceding genera, from *Labrus properly so called* inclusive, may be all regarded as Linnæan *Labri*. We now come to

Genus Xirichthys, Cuv. Which comprehends fishes resembling the *Labri* in form, but they are very much compressed, and the forehead descends suddenly towards the mouth by a deep and nearly vertical line, formed by the ethmoid and the ascending branches of the inter-maxillaries. The body is covered with large scales; the lateral line interrupted; the jaws armed with a row of conical teeth, of which the medial ones are longest, and the pharynx paved with hemispherical teeth; the intestinal canal is continuous, with two convolutions, and no cæca, nor is the stomach in the form of a cul-de-sac. They possess a pretty large air-bladder.

Naturalists, anterior to the time of Cuvier, ranged the species with the *Coryphænæ*, from which they greatly differ in their structure, internal as well as external. They approximate to the *Labri*, to which, however, they are dissimilar in the profile of the head.

Genus Chromis, Cuv. Has the lips and protractile inter-maxillaries, the pharyngeal bones, and dorsal filaments, of the *Labri*; but the teeth are *en carde* upon the jaws and pharynx, with an anterior range of a conical shape. The vertical fins are filamentous, and even those of the abdomen are often prolonged into long filets, and the lateral line is interrupted. The stomach is a cul-de-sac, but there are no cæca. One small species, of a chestnut-brown colour (*Sparus chromis*), is found in immense numbers in the Mediterranean. The Nile produces another, which attains the length of two feet, and is regarded as the best fish occurring in Egypt. It is the *Labrus Niloticus* of Hasselq. and Sonnini. The genus Cychla differs from the preceding by having all the teeth crowded, and placed in a broad band, and by the body being more elongated. Plesiops, Cuv., has the head compressed, the eyes near each other, and the ventrals very long. Malacanthus possesses the general characters of the *Labri*, and the maxillary teeth are also similar to theirs, but those of the pharyngeals are *en carde;* the body is lengthened, the lateral line continuous, the opercle terminated by a small spine, and the long dorsal has only a small number of slender, flexible, anterior spines. One species is found in the Antilles, of a yellowish colour, irregularly rayed across with violet; it is the *Coryphena plumieri*, Lacép. iv. viii. 1.

Genus Scarus, Linn. Comprehends fishes very remarkable on account of the form of the jaws (that is, their inter-maxillary and pre-mandibularybones), which are convex, rounded, and garnished with teeth like scales upon their edges and anterior surface; these teeth succeed each other from behind forwards, so that those of the base are the newest, and in time come to form a range upon the cutting edge. Naturalists have erroneously thought that the jaw-bones themselves were naked or exposed. These jaws are, besides, covered while the fish is alive by fleshy lips, but there is no double lip adherent to the sub-orbitaries. The species have the oblong form of Labrus, with large scales, and the lateral line interrupted; they bear on their pharynx two plates above and one below, garnished with teeth like the pharyngeal plates of the Labri, but these teeth are in the form of transverse laminæ, and not *en pavé*.

Cuvier is of opinion that the *Scarus creticus* of Aldrovandus is the species so celebrated under the name of *Scarus* by the ancients, and in search of which (in the time of Claudius) Elipertius Optatus, the commander of the Roman fleet, went to Greece, with a view to effect its introduction to the Italian seas. It is still used in our days as an article of food in Greece. The species are numerous in the seas of warm climates, and are vulgarly known, on account of the peculiar form of the jaws, and the splendour of their colours, under the name of parrot fishes.

FAMILY XV.—FISTULARIDÆ.

Characterised by a long tube formed in front of the cranium, by the prolongation of the ethmoid, the vomer, the pre-opercles, inter-opercles, &c. at the end of which the mouth is placed, composed, as usual, of inter-maxillaries, maxillaries, palatines, and mandibularies. The intestine is without any considerable inequalities, or many convolutions, and their ribs are either short or wanting. Some of them (the *Fistulariæ*) have the body cylindrical, others (the *Centrisci*) have it oval and compressed.

Genus Fistularia, Linn. Acquires its name from the long tube common to all the family. The jaws are at the extremity, opening but little, and nearly in a horizontal direction. The head, thus elongated, composes a third or fourth part of the whole body, which is itself long and slender. There are six or seven rays in the gills; the osseous appendages likewise extend behind the head to the anterior part of the body, which they tend more or less to strengthen. The dorsal corresponds to the position of the anal, and the stomach, in the form of a fleshy tube, is continuous with a narrow canal, without folds, at the commencement of which there are two cæca. In Fistularia properly so called, there is only one dorsal, which, as well as the anal, is composed chiefly of simple rays; the inter-maxillaries and lower jaw are armed with small teeth;

and between the lobes of the caudal there issues a filament sometimes as long as the whole body; the tube of the muzzle is very long and depressed, the swimming bladder excessively large, and the scales invisible. In the subdivision called AULOSTOMA by Lacépède, a name derived from αυλος, *a flute*, and στομα, *the mouth*, the dorsal is preceded by numerous free spines, and the jaws are without teeth. The body, which is very scaly, is broad, and compressed between the dorsal and anal, the latter followed by a short, small tail, terminated by the usual fin. The tube of the muzzle is rather short, large, and compressed; the swimming bladder very large. We are acquainted with only one species (*Fistularia chinensis*, Bl.), which is found in the Indian seas.

The CENTRISCI of Linn. possess the tubular trunk of this family; the body, however, is not elongated, but oval or oblong, compressed laterally, and sharp on the under side; the gills have only two or three slender rays; the first dorsal is spiny, and the small ventrals are placed behind the pectorals. The mouth is extremely small, and opens obliquely; the intestines are without cæca, folded three or four times; and the swimming bladder is of considerable size. In CENTRISCUS *properly so called*, the anterior dorsal, which is placed very far forwards, has its first spine long and strong, supported by an apparatus connected with the shoulder and head. The species are covered with small scales, and have several broad and denticulated plates on the apparatus just mentioned. The *C. scolopax*, or trumpet-fish, is a very common species in the Mediterranean, about five inches long, and of a silvery lustre. (See Plate CCCIV. fig. 7.) It occurs occasionally on the south-western coasts of England. In the sub-genus AMPHISILE, the back is defended with large scaly pieces, of which the anterior spine and the first dorsal have the appearance of being a continuation. All the species hitherto known to us are from the Indian seas: we may mention as examples, *Centriscus scutatus*, Linn., and *Centriscus velitaris*, Pallas.

We here terminate our abstract of the ACANTHOPTERYGII, or first great order or division of the ordinary fishes.

The second division of common fishes, or that named MALACOPTERYGII, contains within itself three orders, which admit of being characterised by the position of the ventrals, or, in certain cases, by their absence.

ORDER II.[1]—MALACOPTERYGII ABDOMINALES.

These are distinguished by having their ventrals suspended to the under part of the abdomen, and behind the pectorals, without any attachment to the shoulder bone. This is the most numerous of the three orders, and includes a large proportion of the fresh-water fishes. It is divisible into five families.

FAMILY I.—CYPRINIDÆ.

May be known by having the mouth but slightly cleft, the jaws weak and generally without teeth, and their edge formed by the inter-maxillaries; by pharyngeals strongly toothed, thus compensating for the imperfect armature of the jaws; and by the branchial rays being few in number. Their body is scaly, and there is no adipose dorsal, such as is observed in Siluri and salmon. Their stomach has no cul-de-sac, and the pylorus is without cæcal appendages. They are the least carnivorous of fishes.

Malacopterygii Abdominales. Cyprinidæ.

The typical genus CYPRINUS is a very natural one, and comprehends a great number of species, which are readily distinguished by the small mouth, toothless jaws, and the three flat branchial rays. Their tongue is smooth, and the palate provided with a soft and singularly irritable substance, vulgarly known by the name of *Carp's tongue.* The pharynx presents a powerful instrument for mastication, consisting of large teeth attached to the inferior pharyngeal bones, and capable of pressing the food between them, and a stony disk enclosed in a wide cavity under an apophysis of the basilary bone. These fishes have only one dorsal, and the body is covered with scales, most frequently of large size. They inhabit fresh waters, and are perhaps the least carnivorous of their class, subsisting chiefly on grains, grass, and even on mud. Their stomach is continuous, with a short intestine without cæca, and the bladder is divided into two by a constriction.

The genus CYPRINUS,[2] Cuv. including the *Carps* properly so called, has a long dorsal, which, as well as the anal, has a spine for the second ray. Of these, some have barbels at the angles of the upper jaw, and others are destitute of these appendages. Of the former we may cite as an example the common carp; and the gold fish of China affords an instance of the latter.

Cyprinus carpio, the common carp. This well-known fish is of an olive-green, yellowish beneath, having the anal and dorsal spines strong and denticulated, and the barbels short; the pharyngeal teeth are flat and striated on the crown. It is a native of the central countries of Europe; but, owing to its value as an article of food, it was early distributed by human agency over the whole of that Continent. The ease with which it can be transported from one place to another, and its speedy growth and propagation in ponds and artificial reservoirs, afforded great facilities for its rapid dispersion. The year 1614 is assigned as the date of its first introduction into England; but it was naturalized in Germany and Sweden nearly half a century before that period. It delights in tranquil waters, preferring such as have a muddy bottom, and the surface partially shaded with plants. Its food consists of the larvæ of aquatic insects, minute Testacea, worms, and the tender blades and shoots of plants. The leaves of lettuce, and other succulent plants of a similar kind, are said to be particularly agreeable to them, and to fatten them sooner than any other food. Although the carp eats with great voracity when its supply of aliment is abundant,—to such a degree, indeed, as sometimes to produce indigestion, which occasionally proves fatal,—it can subsist for an astonishing length of time without nourishment. In the winter, when they assemble in great numbers, and bury themselves among the mud and the roots of plants, they often remain for many months without eating. They can also be preserved alive for a considerable length of time out of the water, especially if care be taken to moisten them occasionally as they become dry. Advantage is often taken of this circumstance to transport them alive, by packing them among damp herbage, or wet linen; and the operation is said to be unattended with any risk to the animal, especially if the precaution be taken to put a piece of bread in its mouth *steeped in brandy!* In a similar way, the Dutch preserve them by suspending them from the roof of a damp apartment in a bag-net filled with moss, which is continually kept moist,

---

[1] Of the general CLASS of Fishes.

[2] The name is of Grecian origin, and was applied to the species because they were dedicated to Venus, in consequence of their extraordinary fecundity.

and they are fed with vegetables and bread steeped in milk,—a mode of treatment by which they are not only kept alive, but actually thrive and fatten.

The fecundity of these fishes is very great, and their numbers consequently would soon become excessive, but for the many enemies by which their spawn is destroyed. No fewer than 700,000 eggs have been found in the ovaria of a single carp, and that too by no means an individual of the largest size. Their growth is very rapid, more so perhaps than that of any other fresh-water fish, and the size which they sometimes attain is very considerable. In certain lakes in Germany and Prussia, individuals are occasionally taken weighing thirty or forty pounds; and Pallas relates that they occur in the Volga five feet in length, and even of greater weight than the examples just alluded to. The largest of which we have any account is that mentioned by Bloch, taken near Frankfort-on-the-Oder, which weighed seventy pounds, and measured nearly nine feet in length.

Cyprinus auratus (gold fish). This beautiful species, the most brilliantly adorned of all our fresh-water fishes, and scarcely surpassed even by the more richly ornamented inhabitants of the ocean, is well known to be a native of China, although it is now domesticated, so to speak, in almost every country, both of the old and new world. Like the carp, it has the dorsal and anal spines denticulated. When young it is of a blackish colour, and it gradually acquires the fine golden red by which it is characterised; but some examples are of a silvery hue, and others are variegated with three different shades of colour. Like most other animals that have been long estranged from their natural habits, and subjected to artificial influences, this species presents a great many varieties, extending even to some important parts of structure. Individuals occur without a dorsal, others with a very large one, others with the caudal greatly enlarged, and divided into three or four lobes; and in some instances the eyes are enormously dilated.[1] The golden carp is said to have been originally confined to a lake near the mountain *Tsienking*, in the province of *The-kiang*, in China, about the 30th degree of N. lat. It was first brought to England in 1691, but was very scarce till 1728, when a considerable number were imported, and they soon became generally known. They do not flourish in rivers and open ponds, not, however, because such places are uncongenial to them, but because they are exposed to many enemies, against which they have no means of defence. When kept in confinement they ought to be nourished with fine crumbs of bread, small worms, flies, and yolks of eggs dried and powdered, and the water ought to be frequently changed. The ordinary length of this species is from four to six inches; but they have been sometimes known to reach a foot. Although natives of a warm climate, they can sustain a great degree of cold uninjured. An individual, which was accidentally exposed during the night, was completely frozen up in the centre of its glass jar; but as the ice thawed it recovered its vigour, and seemed to suffer no further inconvenience.

To this group belongs the smallest of the European Cyprini, viz. *C. amarus*, which is about an inch long, greenish above, and of a fine red beneath. During the time of spawning, which takes place in April, it has a steel-blue line on each side of the tail; the second dorsal ray forms a rather stiff spine.

Genus Barbus of Cuvier, contains such species as have the dorsal and anal short, with a strong spine for the second or third ray of the dorsal, and four barbels, two of which are at the extremity, and two at the angles of the upper jaw. As an example, we may refer to the *Cyprinus barbus*, or barbel, which may be known by its oblong head. It is very common in clear and running waters, where it sometimes attains to a length exceeding ten feet. Several allied species are found in Italy, having the spine weaker, but which, nevertheless, differ from the following genus by possessing four barbels. Such are *Barbus caninus*, Bonnelli; *B. plebeius*, Val.; *B. eques*, Id. Various species of Barbi occur in the Caspian Sea, in the Nile, and in India; and not a few have been ascertained to inhabit America.

Genus Gobio, Cuv. Has the dorsal and anal short, both of them without spines, and the mouth furnished with barbels. Of this genus the gudgeon (*Cyprinus gobio*) may be cited as an example. It is a small fish, seldom exceeding seven or eight inches, and is found in most parts of Europe in small lakes and gently flowing rivers. It is of a pale olive-brown colour, slightly spotted with black, especially on the fins, the sides and abdomen being silvery white. It spawns in the spring, and as it deposits its ova at distant intervals, the operation generally continues for a considerable time. It is a very prolific fish; and as its flesh is of a very delicate flavour, it is much sought after for the table.

Genus Tinca, Cuv. Unites to the characters of the gudgeons that of having very minute scales; their barbels also are very small. This genus includes the common tench (*Cyprinus tinca*, L.), which is of a deep yellowish brown, sometimes, however, assuming a fine golden colour. Its usual length is from twelve to fourteen inches; but instances are on record of its having reached three feet. It inhabits stagnant waters with a muddy bottom; and in the winter conceals itself among the mud, and seems to undergo a kind of torpidity. In May and June it deposits its ova among aquatic plants; these are very minute, of a green colour, and so numerous that 297,000 have been reckoned in one female. The tench is very extensively distributed, appearing to occur throughout the whole globe. Its flesh is not much esteemed, as it is soft, insipid, and difficult of digestion.

Genus Abramis, Cuv. Distinguished by wanting spines and barbels; the dorsal is short, placed behind the ventrals, and the anal long. Two species are known, the common bream (*Cyp. brama*), and the little bream (*Cyp. blicca*, *C. latus*, Gm. Bl. 10). The former is the largest fish in this subdivision; there are twenty-nine rays in the anal, and all the fins are obscure. It is common in slow flowing rivers and lakes in most European countries. It sometimes acquires two feet and a half in length, but its ordinary dimensions may be stated to be about a foot. Worms, confervæ, and aquatic plants are its usual food; but, like many allied species, it often swallows mud, which renders its flesh unsavoury. "There exists in the river Trent, in the neighbourhood of Newark, two species or varieties of bream. The common bream, *Cyprinus brama*, is known there by the name of Carp Bream, from its yellow colour, and has been taken of nearly eight pounds weight. The other species or variety, which I believe to be a non-descript, never exceeds a pound in weight. It is of a silvery hue, and goes by the name of White Bream."[2]

Omitting the genera Labeo and Catastomus, of which the species are all foreign, and imperfectly known, we now come to the generic group named Leuciscus (Klein), comprehending several kinds indigenous to Europe. They have the dorsal and anal short, and are destitute of spines and barbels, and there is nothing particu-

[1] The varieties of this species have afforded materials for a kind of monograph by Sauvigny, and a painter of the name of Martinet.
[2] *Linn. Trans.* xiv. p. 587.

lar in the structure of the lips. The species of this subdivision are considerable in amount, but they are held in little estimation as articles of food. They are distinguished by the position of the dorsal, a character, however, which is not always sufficiently defined. In some it corresponds to the position of the ventrals; such is the case with *Leuc. dobula* (*Cyprinus dobula*, Linn.), in which the head is broad, the muzzle rounded, and the pectorals red. *Leuc. rutilus* (the roach), has the body compressed and silvery, and all the fins red. In others, the dorsal corresponds above to the interval which is between the ventrals and the anal. This is exemplified in *Leuc. alburnus* (the bleak), in which the body is narrow, and of a brilliant silvery hue; the fins pale; the forehead straight, and the inferior jaws somewhat elongated. It is common throughout Europe; and is one of the fishes whose nacre (or silvery-looking substance) is employed in fabricating artificial pearls. *Leuc. phoxinus* (common minnow) likewise pertains to this group. The appearance of this beautiful little fish is familiar to all. It is the smallest species of the genus found in Europe, the greatest length which it attains seldom exceeding three inches. It first makes its appearance in March, and disappears in October, passing the winter beneath the mud. It is well known to be a gregarious species, and small shoals are to be found in almost every shallow stream, especially in clear weather, as they seem to delight in warmth and sunshine. They usually spawn in the month of June, but their ova are often found at a much later period. The flesh of the minnow is delicate and well flavoured, but its size is too small to admit of its being of much value as an article of food. It is principally used as a bait for the capture of larger kinds.

Certain species of the present genus (the Chelæ of Buchanan) have the dorsal corresponding to the commencement of the anal, and in several of these the body is compressed nearly in the same manner as in some of the *Clupeæ*. Such is *Leuc. cultratus*, which is further remarkable for its lower jaw, which ascends in front of the upper, and for its large pectorals shaped like a scythe.[1] The generic group Gonorhynchus, *Gronov.* is dissimilar from all the other Cyprini, by having the body and the head elongated, and covered, as well as the opercula, and even the membrane of the branchiæ, with small scales; the muzzle projecting in front of the mouth, which is small, and without teeth or barbels; three branchial rays, and a small dorsal above the ventrals. Only one species is known (*Cyprinus gonorhynchus*, Gm.), which is found at the Cape of Good Hope.

Genus Cobitis (loach). Has the head small, the body elongated, clothed with scales, and covered with a mucous matter; the ventrals placed behind, and above them a small single dorsal; the mouth at the end of the muzzle, but little cleft and without teeth, but surrounded with lips fitted for sucking, and by barbels; gill-covers little opened, and having only three rays. Their inferior pharyngeal bones are rather strongly dentated, their intestines are without any cæca, and their swimming bladder, which is very small, is enclosed in an osseous bilobate case, attached to the third and fourth vertebræ. Three species are found in the fresh waters of Europe, viz. *C. barbatula*, *C. fossilis*, and *C. tænia*. The first of these, the bearded loach, is a well-known fish in this country, as it occurs plentifully in almost every small stream. It is about four or five inches long. The second species, which does not occur in Britain, measures sometimes a foot in length. It dwells in the mud of ponds, and is so tenacious of life as to live a long time after being stiffly frozen, or even dried. In stormy weather it rises to the surface and agitates the water. It swallows quantities of air, which it converts, according to M. Ehrman's observations, into carbonic acid. Its flesh is soft, and savours of mud. The third species was introduced into the British Fauna by Berkenhout. Turton says it occurs in the "clear streams of Wiltshire."

The fishes which Bloch distinguished by the name Anableps (a term first used by Artedi, and signifying to raise the eyes, or to look up, being derived from ἀναβλέπω) were long united with the loaches, although they afford characters of a very distinctive kind. Their eyes, which are very salient, and placed under an arch formed on each side by the frontal bone, have the cornea and iris divided into two portions by transverse bands, in such a manner that they have two pupils, and appear double, although in reality there is only a single crystalline and vitreous humour, and one retina,—a peculiarity of which no other instance is to be found among vertebrate animals. The organs of generation, moreover, and the bladder of the male, have their excretory canal in the anterior border of the anal fin, which is thick, long, and clothed with scales; its extremity is perforated, and no doubt subserves the generative functions. The female is viviparous, and the young are not produced till they have attained a considerable size.

The body of these fishes is cylindrical, and covered with scales; there are five branchial rays, the head is flat, the muzzle truncated, the mouth cleft transversely at the end, and armed in both jaws with numerous small teeth. The inter-maxillaries are without a pedicle, and suspended under the nasal bones, which form the anterior edge of the muzzle. The pectorals are in a great measure scaly, and a small dorsal is placed over the tail, and further back than the anal. Their pharyngeal bones are large, and provided with numerous small globular teeth; their air-bladder is very large, and also their intestine; but the latter is without cæca. Only one species is known, which is an inhabitant of the rivers of Guiana. It is the *Anableps tetropthalmus*, Bl. 361. See Plate CCCIV. fig. 8.

Genus Pœcilia, Schn. Has the two jaws flattened horizontally, protractile, slightly cleft, furnished with a series of small and very fine teeth, the upper side of the head flattened, the opercula large, five branchial rays, the body not much elongated, the ventrals not far back, and the dorsal placed just above the anal. They are all small viviparous fishes, and inhabit the fresh waters of America. The only remaining genera included in the present family are Lebias, Cuv., Fundulus, Lacép., Molinesia, Lesueur, and Cyprinodon, Lacép., which comprehend but a limited number of species, most of them of small size, and presenting no peculiarities of particular interest.

FAMILY II.—ESOCIDÆ.

Corresponds to the undivided genus Esox, as established by Linnæus. It is characterised by the want of the adipose dorsal; by having the edge of the upper jaw formed by the inter-maxillary, or at least, when not wholly formed by that bone, the maxillary is without teeth, and concealed in the thickness of the lips. They are a very voracious tribe of fishes; their intestine is short and without cæca, and all are provided with a swimming bladder. With the exception of the *Microstoma*, all the kinds with which we are acquainted have the dorsal opposite the anal.

In the Cuvierian system this family is divided into many genera, of the principal of which we shall now proceed to give some account. Such fishes as belong to

Genus Esox, in its present restricted acceptation, have

[1] The genus Leuciscus contains also the dace, chub, and other well-known British species.

small inter-maxillaries provided with minute pointed teeth in the middle of the upper jaw, of which they form the two thirds; but the maxillaries occupying the sides are without teeth. The vomer, the palatines, the tongue, the pharyngeals, and the arches of the branchiæ, are covered with teeth resembling those of a card; and, in addition to these, a series of long pointed teeth occupy the sides of the lower jaw. The snout is oblong and obtuse, broad and depressed; and there is only one dorsal opposite the anal. The stomach, which is large and plicate, is continuous with a slender doubly-folded intestine without cæca. The swimming bladder is very large. There is only one European species, viz. *Esox lucius*, Linn. (the common pike), Plate CCCIV. fig. 9. During the earliest stage of its life it is of a greenish hue, but in the second year it becomes gray with pale spots, the latter ultimately acquiring a yellowish colour. Its markings, however, are very variable, and instances have occurred of its being perfectly white. It is one of the largest of fresh-water fishes, and indeed, if the accounts which some writers give are not exaggerated, it occasionally attains a size not greatly inferior to the gigantic inhabitants of the ocean. Individuals are recorded as measuring from five to nine feet in length. They frequently weigh above thirty pounds in the lakes of the north of England; and Dr Grierson mentions one taken in Loch Ken, in Galloway, which weighed sixty-one pounds. Bloch indeed examined a portion of the skeleton of another which could not be less than eight feet in length. The most remarkable pike, however, of which we have any authentic account, is that caught at Kaiserslautern, near Manheim, in 1497, which was nearly nineteen feet in length, and weighed 350 pounds. The skeleton of this extraordinary specimen was for a long time preserved, and bore a brass ring with an inscription to the effect that the fish was put into a pond by the hands of the Emperor Frederick II., the 5th of October 1262. From this it is inferred that it was upwards of 235 years old. Pikes are proverbially voracious. There seems indeed to be no bounds to their gluttony, for they devour indiscriminately whatever edible substances they fall in with, and almost every animal they are able to subdue. "It is," says M. de Lacépède, "the shark of the fresh waters; it reigns there a devastating tyrant, like the shark in the midst of the ocean; insatiable in its appetites, it ravages with fearful rapidity the streams, the lakes, and the fish-ponds where it inhabits. Blindly ferocious, it does not spare its species, and even devours its own young; gluttonous without choice, it tears and swallows with a sort of fury, the remains even of putrified carcasses. This blood-thirsty animal is also one of those to which nature has accorded the longest duration of years; for ages it terrifies, agitates, pursues, destroys, and consumes the feeble inhabitants of the waters which it infests; and as if, in spite of its insatiable cruelty, it was meant that it should receive every advantage, it has not only been gifted with strength, with size, with numerous weapons, but it has also been adorned with elegance of form, symmetry of proportions, and variety and richness of colour."[1] A singular instance of its voracity is related by Johnston, who asserts that he saw one killed which contained in its belly another pike of large size, and the latter on being opened was found to have swallowed a water-rat!

The pike inhabits almost all the fresh waters of Europe, but seems to flourish most in the northern and middle countries. It likewise occurs in abundance in Asia and North America. Its flesh is well flavoured and easy of digestion, and is consequently much sought after as an article of food, especially for convalescents, and others of weakly habit. It is most tender and nutritive in young individuals, but full-grown pikes are occasionally found, in which the flesh on the back and near the vertebral column acquires a greenish colour, which is held in high repute, and often purchased at a great price.

Genus Galaxias, Cuv. Has the body without apparent scales, the mouth slightly cleft, pointed teeth of moderate size on the palatines and both jaws, the upper jaw having almost its entire edge formed by the inter-maxillary. There are also some strong hooked teeth on the tongue. The *Esox truttaceus*, Cuv., *Esox alepoditus*, Forst. exhibits the structure above described.

Genus Alepocephalus, Risso. The species of this genus bear a very close resemblance in their general form to those of the preceding group, but their head only is destitute of scales, the body being covered with scales of large size; their mouth is small, and the teeth small and crowded. The eye is very large, and the gills have eight rays. Only one species is known, and it inhabits the deepest parts of the Mediterranean. It is the *A. rostratus*, Risso, 2d ed. f. 27.

Genus Microstoma, Cuv. Have the snout very short, the lower jaw more advanced, and furnished, as well as the small inter-maxillaries, with very fine teeth; three broad and flat branchial rays; the eye large, the body elongated, and having the lateral line garnished with a series of strong scales. There is a single dorsal a little behind the position of the ventrals, and the intestines are similar to those of the pikes. The only species known (*Serpa microstoma*, Risso, p. 356) inhabits the Mediterranean.

Genus Stomias, Cuv. Muzzle extremely short, the mouth cleft almost to the gills, the opercula reduced to small membranous leaflets, and the maxillaries fixed to the cheek; inter-maxillaries, palatines, and mandibles armed with small bent teeth, and the tongue with similar ones. Their body is elongated, their ventrals altogether behind, and their dorsal opposite their anal, on the hinder extremity of the body. We are acquainted with two species of these singular fishes, *Esox boa*, Risso, and *Stomias barbatus*, both from the Mediterranean.

The genera Chauliodus (of which the sole species, found near Gibraltar, is shown on Plate CCCIV. fig. 10), Salanx, and Belone, comprehend a few species found chiefly in the Mediterranean. In the last-mentioned genus, the inter-maxillaries form the whole edge of the upper jaw, which is prolonged, as well as the inferior, into a long snout, and both provided with small teeth; there are no other teeth in the mouth, and those of the pharynx are *en pavé*. Their body is long, and covered with indistinct scales, except a longitudinal carinated range on each side, near the inferior edge. The bones are very remarkable for their fine green colour. The intestines differ in their structure from those of the pikes. One species inhabits the European coasts, which is about two feet long, green above, and white beneath. It affords a good dish, in spite of the prejudice caused by the colour of its bones. It is the *Esox belone*, sea-pike, or *gar-fish*. Species nearly allied are to be found in all seas. Of these, one is said to reach eight feet in length, and its bite is reported to be dangerous.

Genus Scomber-esox, Lacép. Has a snout of the same structure as in *Belone*, nearly the same appearance and arrangement of the scales, but the last rays of the dorsal and anal are detached in spurious fins, as in the mackerels. One of them occurs in the Mediterranean, viz.

[1] Quoted in Griffith's edition of the *Règne Animal*. We cannot, however, agree with M. Lacépède in his admiration of the general appearance of the pike, for we think its long lank jaws and sunken eye give it rather a diabolical aspect.

Esox saurus, Bl. Sch. pl. lxxviii. 2, and is also found along the British shores, where it is known under the name of *Egyptian herring*. It sometimes leaps so actively out of the water as to pass over a space of thirty or forty feet. Of the nearly allied genus Hemi-ramphus, Cuv. several species are to be found in the warm latitudes of both hemispheres. Although their flesh is oily, it is of an agreeable taste.

We now come to a tribe of fishes which have attracted much attention, owing to the power they possess of leaping to a great height into the air, and even sustaining themselves in that element for a perceptible time. This faculty, which has caused them to be named *flying fishes*, they owe to the excessive development of their pectorals, a peculiarity which readily distinguishes them from all other abdominal fishes. Their head and body are clothed with scales, and a longitudinal series of carinated scales forms a salient line at the bottom of each flank, as in some of the genera last described. The head is flattened above and on the sides; the dorsal is placed above the anal, the eyes are large, the inter-maxillaries without pedicles, and themselves forming the edge of the upper jaw. The two jaws are furnished with small pointed teeth, and the pharyngeal bones with teeth *en pavé*. Such as present these characters are to be referred to the

Genus Exocetus, Linn., a name which signifies *lying out*, and which was given by the ancient Greeks to a fish that was reported to be in the habit of coming to repose on shore. They are further characterised by having ten branchial rays, a very large swimming bladder, and straight intestines without cæca; the upper lobe of the caudal fin is the shortest.

The *Exocetus volitans*, Bloch, 398 (see Plate CCCIV. fig. 11), is a well-known flying fish of the ocean (but not to be confounded, as it has sometimes been, with the *Trigla volitans*, or flying gurnard, already alluded to under the genus Dactylopterus). It is common in many of the warmer parts of the northern hemisphere, especially between Teneriffe and the line. It is also said to occur occasionally in the Mediterranean, and may be recognised by its large eyes, and the smallness of the ventral fins, which are placed in advance of the centre of the body. Its mouth is slightly tubular, its scales deciduous, and its size from six to twelve inches. A species more common in the Mediterranean is the *E. exiliens*, Bloch, 397, of which the ventrals are long, and placed behind the centre of the body. It attains to the length of fifteen inches. The young have black bands upon the fins.

Some difference of opinion seems still to exist in regard to the mode of flight in these fishes. Mr Bennet supposes, that because they do not use their pectoral fins in the air precisely as birds use their wings, that their progression ought rather to be termed leaping than flying. "In fish," he observes, "the organ of motion for propelling them through the water is the tail, and the fins direct their course; in birds, on the contrary, the wings are the organs of motion, and the tail the rudder. The only use of the extended pectoral fins in the fish is for the purpose of supporting the animal in the air, like a parachute, after it has leaped from the water by *some power* which is possessed even by the whale. From the structure of the fin, I cannot consider it at all calculated for repeated percussions out of the water; while in that fluid, it continues its natural action uninjured; but it soon dries when brought into contact with the air, and the delicacy of the membrane between the rays would very readily become injured were the organ similarly exerted in that medium. The greatest length of time that I have seen these *volatile* fish on the *fin*, has been thirty seconds by the watch.... Their usual height of flight is from two to three feet; but I have known them come on board at a height of fourteen feet; and they have been well ascertained to come into the channels of a line-of-battle ship, *i. e.* as high as twenty feet and upwards. But it must not be supposed that they have the power of elevating themselves in the air, after having left their native element: on watching them, I have often seen them fall much below the elevation at which they first rose from the water, but never in any one instance could I observe them raise themselves above that height. I therefore regard the elevation they take to depend on the power of the first spring or leap they make on leaving their native element."[1] Colonel Bory St Vincent, on the other hand, regards that opinion as erroneous which limits their aerial movements to a single sudden spring. "Je n'ai pas vu les exocets s'élever très-haut; mais je souvent observe qu'ils ne se replongeaient dans la mer qu'à une bonne portée de fusil au moins du point d'où ils étaient partis. Selon l'occasion, ils changent la direction de leur vol, et s'abaissent ou s'élèvent parallelement aux flots agités; ils ont enfin la faculté de voler d'une manière bien plus parfaite qu'on ne la leur suppose généralement."[2] The double chase of this unfortunate species was indicated by Duquesne so far back as 1690. "Ce petits animaux," observes that voyager, "n'ont nul repos, ni dans l'eau, ni dans l'air; dans l'eau, à cause des bonites, dans l'air, à cause des oiseaux qui fondent sur eux avec plus de rapidite que le faucon ne fond sur la perdrix."[3] Indeed, all voyagers, whether ancient or modern, have recorded the delight with which they witnessed these sudden emergencies; and Bosc in particular describes the flying fish as sometimes rising in hundreds, and even thousands, around his vessel, and darting over the waves in all directions, scouring away, as Coleridge has beautifully said in relation to another group of animals, "like a Tartar troop over the wilderness." We shall conclude this notice by observing that the flesh of flying fishes is savoury and delicate, and that they thus present another claim to the attention of the voyager.

At the end of the family of the Esocidæ is to be placed a genus which differs but a little from them, except in having long intestines provided with two cæca, and which will probably be formed into a particular family.

Genus Mormyrus, Linn. Body compressed, oblong and scaly; tail slender at the base, and enlarged towards the fin; head covered with a thick naked skin, enveloping the opercula and the branchial rays, and leaving for their aperture only a vertical cleft, a circumstance which has caused some naturalists to deny the existence of opercula, although they are as complete as in any other fish, and to assign to them only two branchial rays, although there are five or six. The opening of the mouth is very small, almost as in those Mammalia named anteaters, and the maxillaries form its angles. The teeth, which are slender and notched at the end, cover the inter-maxillaries and the lower jaw; while on the tongue, and under the vomer, there is a band of small and crowded teeth. The stomach is in the form of a rounded sac, followed by two cæca, and a long slender intestine always enveloped in a profusion of fat. The bladder is long, large, and simple. Many of these fishes inhabit the Nile, and they are ranked among the best which that river produces. It is conjectured that it was one of them which the ancient Egyptians held in religious veneration, and which they named *oxyrhincus*.

Malacopterygii Abdominales. Siluridæ.

FAMILY III.—SILURIDÆ.

Is distinguished from all the others in the order by having no true scales, but only a naked skin, or large osseous plates. The inter-maxillaries, suspended under the ethmoid, form the edge of the upper jaw; and the maxillaries are reduced either to mere vestiges, or are lengthened into barbels. The intestinal canal is large, folded, and without cæca; the bladder large, and adhering to a peculiar osseous process; the dorsal and pectorals have almost always a strong articulated spine for the first ray, and there is very frequently an adipose fin behind, as in the Salmonidæ.

Genus Silurus. A numerous genus, known by its want of scales, the mouth cleft at the end of the snout, and, in the greater number of sub-genera, by the first ray of the pectoral being composed of a strong spine. This is articulated to the shoulder bone, in such a manner that the animal at pleasure can either draw it towards its body or erect it perpendicularly, in which case it becomes a dangerous weapon, and inflicts wounds which in some countries are considered venomous, doubtless because tetanus or lock-jaw sometimes ensues. The head of the *Siluri* is depressed; the maxillaries very small; and the covering of the branchiæ wants that piece which has been named by Cuvier the *sub-opercle*.

In some species (*Silurus*, Lacép. properly so called) there is only one small fin, with few rays on the anterior part of the back, but the anal is very long, and reaches nearly to the caudal. In others, more especially so named by Artedi and Gronovius, the small dorsal is without any apparent spine; the teeth on both jaws are like those of a wool card, and behind the inter-maxillary band of teeth there is a vomerian band. Of this kind of structure an example is found in *Silurus glanis*, L. which is the largest of European fresh-water fishes, and the only one of this extensive genus inhabiting the Continent. See Plate CCCIV. fig. 12. It is smooth, greenish black, spotted with black above, and yellowish-white beneath. The head is large, with six barbels. It sometimes attains the length of twelve or fifteen feet, and the weight of 300 or 400 pounds. As this creature is somewhat unwieldy in its motions, it does not pursue its prey, which consists of small fishes, but lies concealed among the mud, and seizes such unwary stragglers as happen to come within reach. It has occasionally been observed in the sea, but always near the mouths of rivers, and in such other situations as to leave no doubt that its appearance there is to be ascribed to accidental causes. The flesh is fat and sweet, and its lard has been employed in some places as a substitute for that of the hog. Sir Robert Sibbald, at the conclusion of his list of river fishes, adds, "Silurus sive Glanis;"[1] from which it has been inferred that this gigantic species may at one period have inhabited the Scottish rivers.[2]

A few fishes, found hitherto only in the Nile, differ from the *Siluri* in having their bodies compressed vertically, and by having a strong and denticulated spine to the dorsal. Their head is small and depressed, the nape suddenly raised, and the eyes placed very low—circumstances which bestow upon them a very singular appearance. They constitute the genus Schilbus. The Pimelodi of Lacépède are characterised by the body being covered only by a naked skin, without lateral armature. This definition, however, comprehends a great number of fishes, many of which present so many differences in appearance and structure, that it is necessary that they should be grouped in several subordinate genera. The first of these, established by Cuvier, and which he names Bagrus, has in each jaw a band of small crowded teeth, and behind those of the upper jaw a parallel band which belongs to the vomer. They admit of still further subdivision, from the number of their barbels and the form of their head. Among those having eight barbels, some have the head oblong and depressed; in others it is broad and short. Of such as are furnished with six barbels, the most remarkable have the muzzle depressed and broad, after the manner of the pike; while others have the head of an oval form, and its shagreened bones forming a kind of helmet. The Pimelodi, however, *properly so called*, have no band of teeth on the vomer, parallel to that of the upper jaw, but there are often some on the palatines. In the number of their barbels, and in the form of their heads, these fishes present still more numerous varieties than the *Bagri*. Thus, among such as have only a single band of teeth, some are observed to have the head helmeted, and a distinct osseous plate or buckler between the helmet and the spine of the dorsal. Such is *Sil. clarias*, Bl. xxxv. 1, 2. In others the buckler is united to the helmet, and forms only a single body with it, the helmet thus extending from the muzzle as far as the dorsal. In some instances the head is oval, clothed only by the skin, through which the bones do not appear; in this group the species have either six or eight barbels. In those called *cat-fish*, the head is naked but very broad, and their barbels also vary, according to the species, from six to eight. We ought probably to place here the *Mathemegh* of the Cree Indians (*Silurus felis*, Gm.?), described by Dr Richardson as found sparingly in the lakes that flow into the Saskatchewan, and more abundantly in the lakes and rivers to the southward. It is much prized as a rich food.[3] Numerous other modifications of structure are to be found in this extensive genus, of which the greater proportion of the constituent species have but recently become known to naturalists. Several have the muzzle elongated, and these lead to a group of still more remarkable conformation, viz.

Genus Synodontis, Cuv. In which the muzzle is narrow, and the lower jaw supports a packet of teeth much flattened laterally, terminating in hooks, and each suspended by a flexible pedicle; a kind of dentition of which no other example is known. The rough helmet, formed by the cranium of these fishes, is continuous, without any interruption, with an osseous plate, which extends to the base of the spine of the first dorsal; and that spine is very strong, as is likewise the case with those of the pectorals. The lower barbels, and sometimes also the maxillaries, have lateral barbels. The species are found in the Nile and Senegal, and are known to the inhabitants of Lower Egypt by the general name of *Schal*, while in the upper regions of the same country they are termed *Gurgur*. Their flesh is not accounted of any value. The Ageneiosi of Lacép. possess all the characters of the *Pimelodi*, but they are without the barbels properly so called. *Silurus inermis* (Bl. 363) affords an example.

Genus Doras, Lacép. Contains such *Siluri* as have a second adipose dorsal, and the lateral line defended by a row of osseous pieces, each relieved by a spine or projecting keel. Their dorsal and pectoral spines are very strong, and powerfully dentated. Their helmet is rough, and is continued as far as the dorsal, as in *Synodontis*, and the humeral bone forms a point behind.

Genus Heterobranchus, Geoff. Has the head provided with a rough, flat buckler, wider than in any other of the *Siluri*, because the frontals and parietals produce

---

[2] Fleming's *British Animals*, p. 198.

[3] *Appendix* to Captain Franklin's first *Voyage to the Polar Sea*, p. 724.

lateral plates which cover the orbit and the temple. The opercle is still smaller in proportion than in the foregoing genera, and the peculiarity observed by Geoffroy distinguishes them from all other fishes, viz. that besides the ordinary branchiæ, they have ramified appendages like trees adhering to the superior branch of the third and fourth branchial arch, and which appear to be a kind of supernumerary branchiæ. All the species pertaining to this genus are found in the Nile, Senegal, and a few of the Asiatic rivers. Their flesh is either of indifferent quality, or altogether unfit for food. This is not the case, however, with the *Sharmuth* or *Black-fish* (*Silurus anguillaris*, Hasselq.), which is common in Egypt and Syria, and constitutes in the latter country a valuable article for the table.

Genus Plotosus, Lacép. Is characterised by a second radiated dorsal, of great length, as well as the anal; and both uniting at the caudal, form a point, as in the eel. Their lips are fleshy and pendent; the throat armed anteriorly with conical teeth, behind which there are others of a globular form, which at the upper jaw pertain to the vomer. The head, as well as the rest of the body, is enveloped in a thick skin, and the branchial membrane has nine or ten rays. All the known species are from the East Indies. They have eight barbels, and, behind the anus, the fleshy and conical tubercle common to all the *Siluri;* and there is, besides, a fleshy ramified appendage, the functions of which, though unknown, are probably remarkable. Some have the dorsal and pectoral spines dentated, and of considerable size. Such is *Platystacus anguillaris*, Bl. 373, while others have them concealed beneath the skin. The latter is the case with *Plotosus cæsius*, Buchan. xv. 44. Certain fishes referred by Linnæus to the genus *Callichthys*, and pertaining to that named Cataphractus by Lacép., have their bodies almost entirely cuirassed, so to speak, on its sides, by four rows of scaly pieces; and there is likewise on the head a compartment of these pieces. The extremity of the muzzle, however, is naked, as well as the under side of the body. The second dorsal has but a single ray in its anterior edge; the pectoral spine is strong, but the dorsal is slender or short. The mouth is but little cleft, and the teeth nearly imperceptible; the barbels, four in number; the eyes small, and placed on the sides of the head. These fishes can crawl for some time on dry land like the eel. In some the pectoral spine is merely rough, in others it is dentate, as in the majority of the *Siluri.*

Genus Malapterurus, Lacép. Distinguished from all the true *Siluri* by having no rayed fin upon the back, but only a small adipose one on the tail, and by the want of a spine to the pectorals, of which the rays are entirely soft. But one species is known with six barbels, the head not so thick as the body, which is inflated in front. It is the famous electric Silurus (*Silurus electricus*, Linn.) of the Nile and of Senegal; the *Raash* or *Thunder* of the Arabs, which gives electrical shocks like the *Torpedo* and *Gymnotus.* It appears that the seat of this faculty is a particular tissue situate between the skin and muscles, and which presents the appearance of an adipose cellular substance, abundantly supplied with nerves.

Genus Aspredo, Linn. *Platystacus*, Bl. Presents very peculiar characters in the flattening of the head, and the enlargement of the anterior part of the trunk, which principally results from the size of the humeral bones; in the proportional length of the tail; in the small eyes placed in the superior face; and in the inter-maxillaries being inclined under the ethmoid, directed backwards, and bearing teeth only on the hinder edge. In addition to these peculiarities, they are the only osseous fishes known which have no mobility in the operculum, because the pieces which ought to compose it are soldered to the tympanum and pre-opercle. Only a few species have come under the cognizance of naturalists, such as the *Silurus Aspredo*, Linn.; *Plat. cotylephorus*, Bl. 372; *Silurus hexadactylus*, Lacép. They have six or eight barbels, and it is remarkable, that when there are eight, one pair is attached to the base of the maxillary barbels; the four of the lower jaw are in pairs, one behind the other. Globules are seen on some of these fishes, which appear to be their eggs, adhering to the thorax by means of pedicles.

Genus Loricaria, Linn. Is so named on account of the rigid angular plates which completely cover the body and head, as with a coat of mail, and is further distinguished from such kinds as possess a somewhat similar defensive armour by having the mouth pierced under the muzzle. In position and mode of conformation, this mouth is most analogous to that of *Synodontis;* the inter-maxillaries are small and suspended under the muzzle, and the mandibular bones, which are transverse and separate, bear long flexible teeth, terminating in a hook.. A broad, circular, and membranous veil surrounds the aperture; and the pharyngeal bones are garnished with numerous teeth *en pavé.* The true opercula are immoveable, as in *Aspredo*, but two small, moveable, external plates seem to perform their office. The branchial membrane has four rays; and the first rays of the dorsal and pectorals, and even of the ventrals, are strong spines. There is neither cæca nor air-bladder. The species may now be arranged in two sub-genera, viz. Hypostoma, Lacép., which has a second small dorsal, provided with a single ray, as in *Callichthys.* Their labial veil is simply papillose, and bears a small barbel on each side. They have no plates under the belly, and the intestines, which are spirally convoluted, are as slender as a pack-thread, and twelve or fifteen times longer than the body. They are caught in the rivers of South America. *Loricaria plecostomus*, Linn., Bl. 376, and *Hyp. etentaculatum*, Spix, iv. are examples of this sub-genus. Loricaria, properly so called, has but a single dorsal in front: their labial veil is garnished on its edges with many barbels, and sometimes covered with villosities; the belly is defended by plates, and the intestines are of moderate thickness. To this group belong *L. cataphracta*, Linn.; *L. rostrata*, Spix; *Rinelepis aspera* and *Acanthicus hystrix*, Id.

FAMILY IV.—SALMONIDÆ.[1]

The fourth family of the *Malacopterygii* of Cuvier is composed almost entirely of the Linnæan genus *Salmo*, and has in consequence received from modern Ichthyologists the title of Salmonidæ. It will remain, however, to future observation to determine whether the family shall take its title from the salmon, as typical of the form, or from some other group, leaving to the above-mentioned fishes the value of a sub-family only. As it is, the circumstance of the present Salmonidæ possessing a small adipose fin, placed between the dorsal fin and the tail, has been used in a light purely artificial, and too much consequence has been attached to it. Mons. Agassiz is of opinion that the Clupeæ should be added to them, as differing only in the want of this fin; while all the Salmones of Cuvier do not possess a true adipose fin,—that part being composed of rays in the genera *Serrasalmus* and *Myletes.*

The family, as it now stands, may be characterised by

[1] As an illustration of the Salmonidæ, we here figure (from Mr Griffith's *Animal Kingdom) Salmo Canadensis*, a North American species, beautifully spotted with blood red on a white circle. See Plate CCCV. fig. 1.

Malacopterygii Abdominales. Salmonidæ.

a lengthened form, the body covered with scales of no great size, and furnished with two dorsal fins. The first dorsal fin is composed of soft rays; the second, generally of a fatty substance, resembling a fold of the skin, is usually of small size. The tail is remarkably powerful, acting as an elastic lever, and, as usual, constitutes the principal organ of locomotion. The margins of the jaws are formed by the maxillary and inter-maxillary bones, and, with the vomer and palate bones, are commonly thickly studded with teeth, strong, conical, and bending backwards. The maxillary and inter-maxillary bones constitute a single continuous arch, as in the higher animals. The pyloric portion of the stomach is furnished with numerous appendices connected with a pancreas. The swimming bladder is large and oblong, and opens into the gullet near the extremity. They are voracious, feed on insects, the less Crustacea, and small fishes. Many of the species are migratory, and approach the mouths of rivers, or ascend their streams for the purpose of spawning. In the breeding season they are marked by some appendage peculiar to the time, or by a change to colouring of more brilliant tints. They reach a large size. The flesh is well flavoured and wholesome.

In the modern arrangement it was found necessary to separate the SALMONIDÆ into groups; and in the present sketch we shall follow those proposed or adopted by Baron Cuvier in the last edition of the *Règne Animal*,—having deeply to regret that his decease should have prevented his great ichthyological work from advancing to a branch of the subject which still stands in need of revision, and which would undoubtedly have derived the most signal advantage from the exercise of his critical skill.

GENUS SALMO, Cuv. Edges of the upper jaws formed by the maxillary and inter-maxillary bones, which, with the palatine bones, vomer, and tongue, are armed with strong conical recurved teeth; rays of the gill-covers from ten to twelve; tail very powerful; posterior dorsal fin adipose; ventral fins placed opposite the anterior dorsal, anal opposite the posterior; vertebræ from fifty-six to sixty. The male fish has the nose elongated and the under jaw hooked during the breeding season. The silvery colours change to gray and red. The species inhabit the sea and fresh waters. Some migrate at the breeding season; all spawn in shallow streams, and both sexes assist in forming the spawning bed. They inhabit Europe, Asia, and America.

The fishes which constitute this genus are of great importance, and are by far the most esteemed and valuable of all those which inhabit the fresh waters. The value of the fisheries, with the number of men engaged in them, is very great, and the expense of the materials which are consumed in the capture of one or two species is immense. In Britain they are mostly consumed in the great towns, either in a recent or prepared condition. In the north of Europe and America numbers are salted or otherwise cured for exportation. At the commencement of the genus is generally placed

Salmo salar, or *common salmon*, a species which likewise occupies the foremost place in the estimation of both sportsman and epicure. The salmon is a fish of great elegance, combining a form fitted alike for strength and swiftness; and its depth and thickness, while in good condition, are so proportioned to its length as at once to convey the idea of a pleasing symmetry. The body above is of a rich bluish or greenish gray, changing below to silvery, sprinkled above the lateral line with rather large sub-cruciform black spots, a few of which at the shoulders generally extend below the line. The characters which distinguish it from its British congeners are the different form of the opercular bones, which show a rounded outline to the posterior edge of the gill-covers, the longest diameter of which to the nose would be in a line through the eye, while in all the other British migratory species the same line would pass much below the eye. The black inner surface of the pectoral fin is nearly a constant mark. The tail is forked in the young state, but fills up to a nearly square outline in the adult, in which the width between the extremities is proportionally wider than in *S. eriox*, the only migratory species which attains a weight at all approaching that of the salmon. The outline of the scales also presents distinguishable differences.

The common salmon inhabits the seas around Great Britain, and extends to the north of Europe and to Asia; but it is not properly ascertained that those found in North America are identical. Its true abode may be called the sea; for as soon as it has entered the rivers it begins to deteriorate in condition, the scales lose their brilliant silvery lustre, and the flesh becomes soft and pale. It is drawn to the fresh waters by that natural instinct so wisely implanted for the purpose of its reproduction, an instinct which enables it to stem the current of the most rapid rivers, to ascend precipitous falls, and to pass through weirs and obstacles of human intervention, which no other power could overcome. This desire of looking for a suitable place in which to deposit their ova is their sole reason for thus seeking the "rivers of water," the torment of sea insects, or other causes which have been assigned, having no influence. This may be at once understood from the fact of the barren fish continuing their usual haunts along the coast, while a great many do not for a year at all enter the fresh waters. It is during this run to the proper spawning beds that the greatest numbers are captured, either by weirs, cruives, nets, or the rod; and it is then also that the sporting angler alone can ply his vocation, almost all attempts to angle the salmon in salt water having yet proved unsuccessful. Many fish far advanced with spawn are by these means destroyed; for unfortunately the most advanced are the most voracious, and a needy fisherman looks more to his present gain than to an expected produce of another year. It would be well and wise if the net fisheries of this valuable species were more confined to the tide-ways, where, in some estuaries, they are extensively carried on (as well as in the rivers) by means of stake-nets. These are so constructed as to intercept the fish entering the rivers, all in a high state of condition, and are sometimes wrought to such an extent as to employ several miles of netting.

Salmon generally delay entering the rivers in great numbers until the streams become somewhat swollen by rains, although in the larger rivers there may be said to be a limited daily run. When the flood has fairly mingled with, and to a certain extent has saturated, the estuaries, the rush of fish is often very great, especially if there has been a continued tract of dry weather. In the latter case they collect at the mouths of rivers, and are seen and often taken in vast numbers; but they do not then attempt an ascent, deterred perhaps by the clearness of the stream, or by some instinctive feeling that the water would yet be deficient to carry them through. As the *fresh* approaches, however, an increased activity may be perceived; and, as far as we can judge, the change is probably indicated by the nostrils receiving a sense of the mixture of the waters, by means of the large ramification of nerves with which they are supplied; and to this same sense may perhaps be attributed the singular fact of the greater proportion of salmon returning to the very streams in which they were spawned. The fish, on entering the river, rush forward as long as the flood continues, seldom resting in their course during the time that the water continues discoloured. From ten to twenty-five miles daily is the rate, as far as can be ascertained, at which they are supposed to travel.

In their more lengthened courses, where the rivers are deeper and the interruptions less frequent, the rate at which salmon travel is probably much more rapid. We know indeed little as yet regarding the identity of species between our own and those of foreign regions, but if, as some suppose, our salmon attains to the lofty Cordilleras of South America, by means of the mighty Maragnon, then it must run a course of about 800 leagues. Bearing in mind, however, that the salmon is a truly northern fish (that they occur in *some* abundance in the arctic regions, may be inferred from the fact, that Commander Ross, during his recent voyage, took *three thousand three hundred and seventy-eight* at one haul, in the month of July; and that his uncle Sir John obtained a *ton weight* of salmon from an Esquimaux, in exchange for one or two knives!), and also remembering those laws of distribution which regulate, and, with a few exceptions, circumscribe, the localities of living creatures, we think it more than likely that the South American salmon belong to another species. We know, however, that our common kind (*Salmo salar*) makes its way by the Elbe into Bohemia, and through the Loire as far as the environs of Puy, in the ancient Velay. We also know that it works its way up the Rhine, and visits a portion of the rivers of Switzerland, although the irresistible torrent of the Falls of Schaffhausen prevents its ingress to any part of the basin of the great Lake of Constance. But we feel less assured of its occurrence in the Persian Gulf, or of the identity of the species found in the Caspian Sea. Neither can we credit that it advances unrepelled by the gloomy terrors of a subterranean journey, and that salmon from the Gulf, adorned by the fanciful Persians with rings of gold and silver, have been found in the Caspian. The non-existence of the supposed communication is of itself a pretty sufficient barrier, even did no other exist in the laws of nature, and were light and atmospheric air dispensable.

In our lower and clearer waters, however, they travel at a much slower rate than that above alluded to,—resting for some time in the pools by the way, and now and then taking a regular *lie* in some chosen spot, which they will return to daily as long as the river continues unfitted for their progress. Upon the least accession, however, to the water, either directly or from some swollen tributary, they are again upon the alert; and it is often felt by them several hours before the quickest or most experienced human eye can perceive a rise upon the river. Having ascended to a considerable height, they remain more stationary, and proceed more slowly with the subsequent floods, till the spawn increases in size. This increase, if not influenced by, is at least so connected with, the commencement of the colder weather, as then to proceed at a more rapid rate. As the spawn advances, the symmetry of the form is disfigured; the female becomes disproportionately large, the colours lose the brightness of their silvery tints, and become dull and gray. The male becomes thin upon the back, the nose elongates, and the under jaw turns up in a large and strong hook, which enters a hollow in the nose before the inter-maxillary bones. The colours and markings become brown and red, those on the head and gill-covers being particularly brilliant, and disposed in lines almost like the marking of a *Sparus*.[1] In this full breeding dress the male and female seek some ford or shallow stream, and commence to excavate a trench or furrow (chiefly by the exertions of the female). In this the spawn is deposited, and impregnated at the same time, and finally covered with gravel by the exertions of the fish. The furrow is generally from six to nine inches in depth; and when the spawn has appeared to be covered beyond that depth, this has occurred from some other circumstances,—such as the stream or floods having carried downward additional masses of gravel, &c. After this great effort has been accomplished, both sexes are reduced to a state of remarkable emaciation. The elongated nose, and hooked jaw, and brilliant colours, are almost immediately lost; the old scales are cast, and the fish retire to some pool to regain their strength and complete their new clothing. They finally redescend to the sea by easy stages, where their former condition and silvery lustre are regained, their strength invigorated, and all their functions so repaired as to enable them ere long to renew their visit to the flowing streams, again to multiply their race.

The ova continue covered by the gravel during the winter, and begin to vivify from about the end of March to the commencement of April. The fry remove from under the gravel when nearly an inch in length, with the ovum still attached; and at this period, if the spawning bed or furrow be turned up, it will appear in motion. When disengaged from the ova, the fish increase in size most rapidly, and about the end of April and during May commence and perform their first migration or journey to the sea. At this time they are from four to six inches in length, of a greenish gray above, silvery below, the scales extremely delicate and very deciduous. From the time they reach the sea, for two months or ten weeks, we lose sight of them, and can only infer their growth from the fact, that after the lapse of that period we find them again ascending the rivers with a weight of from two and a half to four pounds. They are then known under the name of *gilse* or *grilse;* and their size, as they ascend from the sea, increases with the advance of the season. The gilse which thus ascend spawn during the ensuing winter, and are then entitled to the name of *salmon*. Descending in a weak state (as before mentioned), they return again in the summer of the following year, as fish of from ten to fifteen pounds weight, according to special circumstances. A third year would still increase their weight, as would several ensuing seasons, till the attainment of an enormous size. Pennant, for example, mentions a salmon which weighed seventy-four pounds; and although we now regard with something of wonder a fish which weighs even the half of that amount, yet there is no doubt that not many years ago salmon of forty pounds were much more frequent than in these degenerate days.[2] The absence of salmon of the largest class from many of the Scotch rivers, where they formerly abounded, is in fact owing to the injudicious perfection of our fisheries, which occasions the constant capture of the species in the state of gilse, or other early condition; and the chances are by consequence greatly against any individual escaping the various dangers by which it is environed, for such a succession of years as is likely to admit of its attaining to its full dimensions. The destruction by poachers in the higher parts of the rivers, of the large enfeebled *kelts*, or fish which have completed their spawning operations, is also extremely prejudicial; for these individuals (almost utterly useless as food at the time alluded to) would, if allowed to descend to the salubrious sea, ere long revisit their native streams, greatly increased in size, and full of health and vigour.[3]

---

[1] In this state it has received from Cuvier the erroneous name of *S. hamatus*, as if it were a distinct species. See *Règne Animal*, t. ii. p. 303.

[2] We observe that a salmon above fifty pounds weight was recently taken at the mouth of the Leven in Dumbartonshire. The general capture this season (1835) has been very great in Scotland. Nearly 800 were taken at one haul in a bay of the island of Islay; and our calculation, from accurate data, is, that for some time past about a *hundred thousand salmon* (including grilse) have been shipped in Scotland *weekly* from our eastern ports alone. A friend of our own lately saw a salmon of sixty-one pounds weight on a fishmonger's stall in London.

[3] The reader will consult with advantage the *Parliamentary Reports* of evidence taken by a Committee of the House of Commons,

Malacopterygii Abdominales. Salmonidæ.

Salmo eriox, or *bull trout*, is another British species which attains a large size, and does not seem as yet clearly described as inhabiting any of the other European waters.[1] It reaches a weight of twenty-five pounds. It is thicker in proportion to its length than the salmon; the fins are much more muscular; the tail particularly so, and perfectly square at the end in all the stages of growth, while the distance between the two extremes of the web is smaller proportionally than in any of the other species. The head is larger in proportion than that of the salmon of a similar weight, and the opercular covering is more lengthened. The toothing is very strong. The general colours are, above greenish gray, the lower parts silvery white; the body above the lateral line being thickly covered with large cruciform black spots. In the breeding dress they assume a much blacker tint than the salmon, and want much of the red markings. All the under parts, jaws, and cheeks, become blotched with deep blackish gray. The flesh is of a yellowish tint, and is coarse, except in the young state; it has the least flavour, and is consequently less esteemed in the market than any of the other species. The hook of the under jaw of the male does not become so elongated as in the salmon. The old fish commence to enter the rivers about the end of July, and appear to deposit their spawn and return to the sea about a month earlier than the salmon. The young fish, of from two to three pounds weight, and in this state known as *whitlings*, enter the rivers about the beginning of June. In all its states it is a very powerful fish, and feeds voraciously and indiscriminately. When hooked it springs repeatedly from the water, and runs (to use an angler's expression) with extraordinary vigour to free itself. The river Tweed and its tributaries are among the principal localities for this fish. It occurs also, though more sparingly, in some of the rivers of the Solway, but appears to be rare on the west and north coasts of Scotland.[2]

Salmo trutta and *albus*.—These fish have been by most modern Ichthyologists described as distinct. The characters of each, however, are extremely difficult to determine; and it is most probable that they will both be found to merge into one species, entitled to the name of *Salmo trutta*. Both fish are very abundant, and are taken in great quantities in the Solway and its tributaries, and along the greater part of the west and north coasts of Scotland. In the first-named locality, they bear the name of *sea trout*, *herling*, and *whitling*; in the two latter, of *white trout* and *finnock*; and being transported to the markets of our metropolis, they receive the additional name of *salmon trout*. Thus we may easily conceive the immense confusion that may and has arisen from the use or abuse of provincial names. Along the south-east coast of Scotland they appear less abundant; but this may arise from the larger mesh employed in the nettings. The Tay and the Forth supply the Edinburgh market. In its largest state, or as known under the specific title of *trutta*, it enters the rivers from two and a half to six pounds weight in the end of May. It is of an elegant form, and possesses all the symmetry of the salmon. The head is small, the back remarkably broad when viewed from above; the tail slightly forked, and wide at the extremity of the web; the colour above greenish, inclining to bluish-gray, lower parts of the clearest silver; body above the line spotted, as in *S. eriox*, with large, deep-black spots, but generally much fewer in number. The flesh is pink, richly flavoured, and much esteemed for the table. It ranks next to that of the salmon, and by many is esteemed more delicate than even that prized species. The *S. albus*, or smaller and younger state in which it is found, is very nearly of the same proportion, form, and colours. They approach the mouths of the rivers in the end of July and commencement of August, in immense profusion, and immediately enter the fresh waters, where an angler may take almost any quantity without the exercise of great skill. In the north they form a perquisite to the taxmen or kayners of the salmon fisheries,—above a thousand being sometimes taken at a sweep of the net. In the Solway they are taken in equal abundance in houses of the stake-net, covered for the purpose with net of a small mesh, and are then carried to the various country markets, and during the height of the run to the villages, in cart-loads, for sale. The flesh of this smaller fish (whether species or variety, as the case may be) is also pink, and delicately flavoured. Its food is likewise the same as that of the larger kind; in the sea small Crustacea (*Talitrus locusta* being a favourite and common food),—in fresh water aquatic insects, worms, minnows, or other small fish. They appear also to spawn rather earlier than the salmon, and after the same manner. The colours of both sorts during the breeding season are deep-grayish black, slightly tinted with brown in the males; and at this time they offer a most marked contrast (being black and lean) to the symmetrical form and brilliant silvery tints of their perfect condition.

The preceding species (*S. salar*, *eriox*, *trutta*, and *albus*)—whether three or four in number, is still, as we have said, a dubious point—appear to be the only migratory salmon yet known to inhabit the waters of Great Britain. On the Continent of Europe, however, we have the

Salmo hucho, said to be peculiar to the waters of the Danube, but most probably migratory to the Black Sea, and certainly not a native of the British waters, though inserted in many of our lists. It is a fish of extraordinary power, attaining to the weight of sixty pounds; and is of more lengthened proportions than the common salmon. The flesh pale coloured, and rather coarse. The young have large transverse bands upon the back and sides; with age these break up into spots, and gradually disappear, till the ground colour becomes uniform, and is only broken by the ordinarily black or violet spotting. In America, again, we have in this division the

Salmo Hearnii, or *Copper-mine River salmon*. Above olive-green, pale on the sides, and shading into bluish white, marked with longitudinal rows of flesh-red spots, largest on the sides, where they are about the size of a pea. The scales, like those of the other salmon of America, are much smaller than those of the European species, and in this fish they possess peculiar lustre. The teeth are weak and few, their size inferior to those of the common salmon. Their flesh is red. This fish is abundant during July and August, below the falls of the Copper-mine River.

The migratory salmon are distinguished from those which inhabit only the fresh waters by the clear grayish blue of the upper half of the body, and the brilliant silvery lustre of the belly and lower parts. Among those

---

appointed to investigate the subject of the salmon fisheries. We beg also to refer to Dr Knox's Observations, published in the 12th volume of the *Transactions of the Royal Society of Edinburgh*.

[1] The *young* is the *whitling* of the Tweed, the *Berwick trout* of the London markets; but the *whitling* of all our Scottish rivers is not necessarily the young of *S. eriox*, in as far as provincial names are sometimes variously applied. In regard to the more scientific synonyms of this species, we know not what degree of relationship its adult state may bear to the *Truite de Mer* of the French,—*Salmo Schiefermullcri*, Bloch, 103.

[2] We have no doubt that the *Norway salmon* of the Sutherlandshire fisheries is identical with the above-described species,—that is, with the full-grown *Salmo eriox*.

Malacopterygii Abdominales. Salmonidæ.

which in common language receive the appellation of *trouts*, the colouring is more varied and of brighter tints, in which yellow and orange predominate, changing to various shades according to locality. The best and most familiar example is

Salmo fario, or *common trout*. This lovely fish is most extensively distributed over the whole of Northern Europe, being found in every burn and tarn, in every lake and river. It may be also said to be one of the most pleasing in its appearance; and, when newly taken in "golden glory" from some translucent stream, is exquisitely beautiful. The variation of the tints of the ground colour is infinite; yellow, however, is the most predominant, varying to the most brilliant orange; while at other times the ground colour of the body runs from a dark-greenish black to violet, in most instances numerously spotted with black and red. Sometimes, however, the black is alone present in the form of large round spots, placed in a pale circle, but in all cases beautifully relieved, and breaking up the uniformity of the other colours. In a few instances the spots have been observed to be wanting altogether. One cause of the variation in the trout, is the difference of food; and, according to every information we possess, those which feed on fresh-water shells, *Gammari* (screws, or fresh-water shrimps, as they are sometimes called), are of the most brilliant tint, and also of the finest flavour, with a decided pinkness in their flesh. Those feeding on the ordinary water insects are next in brilliancy and flavour, while such as live chiefly upon aquatic vegetables are dull in colour, and of soft consistence. This is further confirmed by the trout in *stews* being always finished, or *fed off* as it is called, on the foresaid Gammari, collected often from a distance. It is only in this way also that we can account for the variation in the appearance and flavour of trout found in two adjoining bays of the same lake. The individuals, in fact, do not appear to stray to any distance, but seem to be satisfied with whatever food is found within a limited district, and which of course will be in many instances of a peculiar and local kind. It is also true, that the colours of trout accommodate themselves to the tint of the water, and to the prevailing *tone* of the bottom, whether of rock or gravel, or of softer substance; and so constantly is this the case, that an experienced and observant angler has little difficulty in accurately predicating the general aspect of the fish of any lake or river. The presence of moss, so frequent in alpine districts, has invariably the effect of deepening the tints, particularly the shades of green and yellow.

In form this fish, when in perfect condition, may be said to be nearly symmetrical; the head only being sometimes rather large in proportion to the body, when considered in relation to what we regard as the *beau ideal.* The fins are of moderate strength, those of the body assuming a variation of form, from a rounded to a lengthened extremity. The tail is almost always forked; the fins are always coloured, that is, never of the transparent whiteness observable in the migratory species; and their tints are generally of a paler shade than those of the corresponding parts of the body. The anal fin is often bordered on its lower surface with white. The scaling is proportionally less than in the migratory kinds. The toothing is in general strong, and very prominent on both the tongue and vomer.

The average growth of the common trout, taking the species generally, may be stated at about a pound, and certainly not more than a pound and a half. In almost all rivers, fish weighing beyond this may certainly be found; but they are comparatively uncommon. Individuals from two to six pounds weight are occasionally taken, even in what may be termed a "wild state." In ponds or stews, again, they reach a much greater size, but cannot be said to be in the natural condition of unenclosed fish. The Thames trout seem to reach most frequently the largest size, being short compared to their length, but of great thickness and well flavoured. Two were lately taken, the one of eleven, the other of fifteen pounds weight. The lakes in the north of England produce trout of very fine quality, and which are often passed off for char. Loch Leven, too (of which the barren isle and now dismantled castle are famous in history as the prison-place of the beautiful Queen Mary), has long been celebrated for its breed of trout. These, however, have fallen off of late considerably in their general flavour and condition, owing, it is said, to the partial drainage of the loch having destroyed their best feeding ground, by exposing the beds of fresh-water shells, which formed the greater portion of their food. Farther north (as in Sutherlandshire) the immense multitude of lochs produce a corresponding abundance and variety of trout. Of these, however, only a few are of superior quality; but these few may assuredly vie with the trout of any country in the world.[1] Another large species, occurring in the British waters, and not yet distinctly known elsewhere, is the

Salmo ferox, Jardine. This species reaches a weight of twenty-eight pounds, and is of very great power compared with its size. The characters which distinguish this fish from *S. fario* are the great size which it attains in a natural state, the large proportional size of the head, the square extremity of the tail in all the stages of its growth, the relative position of the fins, and the number of rays in the dorsal, which vary from 2—11 to 4—11. The external skin or covering of the scales is also extremely tough; and there is a difference in the form of the scales of the lateral line. In colour the upper parts are generally of a deep purplish brown, shading into purplish gray, and finally, on the lower parts, to greenish or grayish yellow, more or less tinted with orange. The spotting is large and not numerous, and consists of black spots placed in a pale circle, and of large pink spots with a similar light area. These extend over the gill-covers, upper fins, and often over the tail itself. A variety occurs in Loch Loyal, in Sutherland, above purplish brown, beneath blackish gray, the whole body spotted over with dark sepio-coloured spots, of a smaller size on the lower portions. *Salmo ferox* appears to be entirely confined to the lakes, seldom ascending or descending rivers, or wandering in and out of them, and never migrating to the sea. When spawning, it ascends for a short way up the rivers or streams which run into the lakes, but never, as far as yet known, descends those which run out of them. It inhabits, among the English lakes, Ulswater; but does not there reach a size above ten or eleven pounds. In Ireland, as far as we can yet learn (specimens having not yet reached us on this side of the water), it is found in Loch Neagh and some other large lakes; and in Scotland we have taken it in Loch Awe, Loch Laggan, the upper end of Loch Shin, and Lochs Loyal and Assynt. It is a fish of remarkable ferocity, and as great an enemy to its smaller companions as the pike. It may be taken by night lines, or by strong trolling tackle, baited with a small trout, and will return a second and third time to the bait, even after it has been dragged for forty or fifty yards.[2]

---

[1] We may here note the existence of a strongly marked and peculiar variety, called the *gillaroo trout* of Galway. It is remarkable for feeding on shell-fish, in consequence of which (as is supposed) the coats of the stomach acquire a great degree of thickness,—from which peculiarity it is sometimes called the *gizzard trout*.

[2] For a detailed account of the mode of fishing for this and the other species, see our article ANGLING, in the third volume of the present work.

Malacopterygii Abdominales. Salmonidæ.

S. salmulus, or *parr*. An abundant species in all the clear running streams in England and Wales, and the south of Scotland; but in the last-named country it begins to decrease, so as to become comparatively rare, towards the north. It frequents the clearest streams, delighting in the shallower fords having a fine gravelly bottom, and hanging there in shoals, in constant activity apparently both day and night. It is found during the whole year in the rivers; but its breeding has not yet been discovered, though the fish are found in such a state as to shed their spawn when handled, close to the verge of the tideway. It is a remarkably beautiful little fish when newly taken from the water, above of a greenish gray, beneath white inclining to yellowish, the sides marked with dull bluish patches of an oval form, and the body above the lateral line sparingly spotted with brownish-black and red. On the gill-covers there are two black spots, one of which is often indistinct. This fish has been always confounded, and still is so, with other species. Many maintain it to be the young of the salmon, while others insist that it bears that relationship to the common trout. The presence of the dark finger-like markings upon their sides has naturally assisted in this confusion. These marks, however, are distinguished by being always narrower in their form than in the trout or young salmon.[1] Besides the external aspect being so distinct that any observer will without difficulty separate them when seen together, the whole skeleton of our present species is more delicately formed, as are also the teeth. The form of the opercular bones is likewise different, and the length of the maxillary bones is much less in the *S. salmulus*, or parr, showing a very marked difference when the open mouths of the different fish are exhibited together. Another distinction is, the great width and power of the pectoral fins, evidently a special provision, as the principal organ of support in those rapid streams where this little fish is almost always found.

Although the history of the parr is still, in truth, obscure, we certainly deem ourselves authorized to state that it is not the young of the salmon. It may be found in rivers throughout the year, and is more especially abundant during those midsummer months in which the acknowledged young of the salmon is unknown except as a fish returning from the sea. The most characteristic and irrepressible instinct of the latter seems to consist in its descent to the sea a few weeks after exclusion from the egg; and if our summer parr is also the young of the salmon, the fact presents a very rare and remarkable example of different individuals of the same species varying in their instinctive habits. The occurrence of parr in rivers so long after midsummer, and the entire disappearance of *smoults* (as the young salmon are sometimes called) anterior to that period, is a main argument in favour of their being distinct kinds; and we cannot get over the difficulty by simply asserting, that such as go down to the sea early are parr, and that such as go down late are parr also. It is admitted that the ova of salmon are hatched in spring, and that the growth of the young (by whatever name we choose to call it) is extremely rapid. Now, as nobody ever finds a parr above a few inches long (six inches is a large one), and as by the end of summer they must be several months old, how can we (in the belief of their being young salmon) reconcile their imputed age with their actual dimensions?[2] Still more difficult will it be to explain, in connection with that belief, how the brood which has descended seawards in the spring should, after the lapse of the same period, be found in their native rivers weighing many pounds.

The preceding are all the species belonging to our present group which have been yet ascertained to inhabit the waters of Britain. On the Continent of Europe we have the *S. lacustris*, Linn., found in the lakes of Lower Austria, and in the Rhine above Constance, and reaching to an enormous size.[3]

In the northern parts of North America, according to Dr Richardson, trout abound in every lake and river. In the *Appendix* to that gentleman's first expedition under Captain Franklin, the different varieties are all placed under *S. fario*, or common trout. It is doubtful, however, whether that species exists at all in America; and several species entirely distinct will be described in the third volume of the *Northern Zoology*, which have much of the colouring of some varieties of the European trouts, but differ remarkably in the smallness of the scales.[4] Specimens of forty pounds in weight were seen; and in Lake Monito they were said to attain the weight of ninety pounds.

Another small group, which has hitherto been placed among the true Salmones, contains the fish commonly known under the name of *Char*. They differ from the trouts in the very small and narrower form of the scales, in the more delicate toothing (the vomer furnished with a single minute tuft at the tip, instead of being armed for its whole length), in the remarkably brilliant change which takes place during the season of breeding, a change very much more completely developed than in any of the other

[1] We would also suggest, as a good logical argument against the fact of *S. salmulus* being the young of the common salmon, that it is frequent in streams where salmon are scarcely ever seen. "What a pity it is," observes the Rev. George Low, "that I am almost obliged to deny the salmon a place in the Orkney zoology; yet true it is, that this noble fish is so seldom got here, that it is considered as a *wonder* when one is thrown ashore, or runs so far up one of our burns as to be taken. I have not heard of above three or four instances of salmon being taken in Orkney, three of which (if they were all salmon) were killed and brought on shore by the otter from the sea, and picked up by the country people, and a fourth which stuck in a mill-wheel, and was caught by the miller." The same writer, under the article *Parr*, observes, "Pretty *frequent* in the shallower lakes and clear burns, though not in such numbers as I have observed them in Scotland." (*Fauna Orcadensis*, pp. 220 and 223.) The reader will also bear in mind, that as we advance northwards in our own island, the parr becomes scarcer, the salmon more abundant,—and that while in the icy streams of the arctic regions the former has not yet been detected, the latter swarms in (elsewhere) unequalled numbers. It is scarcely worth while to allude to the opinion maintained by the late Sir Humphry Davy and others, that the parr is a hybrid or mule between the trout and salmon!

[2] We yesterday (14th September 1835), while angling in the North Esk, above the beautiful residence called The Burn, in Kincardineshire, killed about a dozen parr, two of which, measuring eight inches in length, were the largest we had ever seen. They were, however, as usual, spotted with red along the lateral line, and tinged all over the under parts, like trouts, with yellow. They exhibited no approach to the silvery character of the salmon, nor any departure from the usual aspect of the parr. The majority of the others were of the ordinary size, and some of them so small as to render it entirely incomprehensible—unless we are totally misinformed regarding the spawning periods of the salmon, and the time of its exclusion from the egg—by what process of reasoning they could be maintained to be the young of that fish.

[3] We are not yet in a position to judge conclusively regarding the identity or distinction of the great lake trouts of Switzerland, and our own *Salmo ferox*. "La grande truite du Lac de Genève (*Salmo lemanus*, N.)," says Baron Cuvier, "qui se trouve aussi dans quelques lacs voisins, a la tête et le dos semés de petites taches rondes et noirâtres sur un fond blanchâtre; *sa chair est très blanche*. Il y en a de quarante et de cinquante livres." (*Règne Animal*, ii. 303.) Now the gigantic tyrant of our Scotch lochs, to say nothing of other discrepancies, has the flesh of an *orange hue*.

[4] The greater number of the plates for the volume above alluded to have been for some time engraved, and their publication, with the corresponding descriptions, will afford an important addition to the library of the Ichthyologist.

species, and in their food consisting in a great measure of minute entomostraca. The best and most familiar example of this group is the char of England.

Salmo umbla, Agassiz,—apparently confounded by most authors, in consequence of its great variety of aspect, and synonymous, according to the above-named naturalist, with *S. alpinus* and *salvelinus*, Linn. It is abundant in the English and Welsh lakes, and in the greater number of those in the north of Scotland, when of any considerable extent; but more seldom seen there, from the absence of the practice of *netting*, and the general unwillingness of char to take a fly or bait. This fish is of great repute in the Lake of Geneva, and is also found in many of the alpine lakes of northern Europe. The common char reaches a considerable size, being sometimes taken in Britain above two pounds in weight, although the more usual weight is under three quarters of a pound. When in full condition, it is a fish of very great beauty, above of a grayish green, shading into the most delicate white on the lower parts, and tinted with a blush which is comparable to that seen on the breasts of some of the gull tribe when newly shot in spring. The body is sprinkled over with pale spots of a considerable size. In this state they remain in the deeper parts of the lakes, and are not frequently taken, although we doubt not they might be so were the practice adopted of hanging a herring-net in the deep water, instead of trying only the *winter* practice of hawling in shore. We ourselves caught them by the former method, in their prime *silvery* state, in Sutherland, during the month of June. On the approach of the breeding time, they seek the mouths of the small tributaries, and are taken in vast numbers at the very period when their preservation ought to be most strictly attended to, and when, in truth, they begin to fall off in their condition. At this season the colour of the upper parts is darkened, the fins are very rich, and the sides and belly become of a beautiful and brilliant red, the whole spotted with small marks of a paler tint.

Although we here follow our friend M. Agassiz in placing the two supposed species under one denomination, yet we willingly admit, and indeed particularly desire our readers to remember, that the history of the char, whether single or distinctive, has not yet been clearly made out.[1] We have already mentioned (in the article ANGLING of this work) that both kinds occur in Windermere, to wit, the char or case char (*Salmo alpinus*), and the torgoch or red char (*Salmo salvelinus*). These are usually thus distinguished:—the former by having the first rays of the ventral and anal fins white; the latter by having those parts plain, that is, of the same colour as the other rays. A remarkable distinction is also observable in their natural habits,—the case char ascending rivers, and spawning about Michaelmas,—the red char depositing its ova along the shores of the lake, and not till the end of December or the beginning of the year.[2] Let these facts be duly regarded in determining upon the distinction or identity of species. We hope ere long to investigate the subject steadily. In the mean time, to illustrate the character of colour, we shall extract from our note-book some memoranda made a few seasons ago, on six specimens of char (supposed to exhibit examples of the different varieties or kinds) selected from a hawl taken (by net) in Windermere on the 12th December. "No. 1 is a very beautiful fish,—the ground colour of the body pale ashy brown, somewhat lighter beneath the lateral line. The sides are richly marked with scarlet spots of different sizes; the whole of the under surface, from the pectoral fins to the tail, are brilliant scarlet. The fins are margined anteriorly with an opake white stripe, followed by a blackish-brown portion, passing posteriorly into deep crimson. The tail is blackish brown. The nose and front part of the head are marked by a black spot. The dorsal fin is of the same pale-brown colour as the back, slightly inclining to blue." This seemed a male. "No. 2 is a smaller fish, brown upon the back, and becoming gradually paler beneath; the abdomen and lower parts are dingy white, tinged with bluish colour. The ventral and anal fins are margined with white, their other parts flesh colour; the pectoral fins are reddish brown; the dorsal fin and tail blackish brown. The sides of this specimen are indistinctly marked with pale yellowish-red spots." This was a male red char, which appeared to have spawned. "No. 3 is of a blackish-brown colour, somewhat silvery, paler beneath the lateral line, and passing into yellowish white on the belly. The pectoral, ventral, and anal fins are brown, tinged with red. The dorsal fin and tail are brownish black. The upper part of the head is also black. The sides of this specimen are distinctly marked with numerous very pale, almost colourless, spots. No. 4 resembles the last described, but is smaller." These the fishermen called two *geld fish*, full grown and half grown. "No. 5 is a very dark fish, brownish black upon the back and sides, becoming, as usual, gradually paler beneath the lateral line. *The pectoral, ventral, and anal fins are distinctly margined* anteriorly with opake white; the central portion of these fins are brownish black, and their interior margins flesh colour. The upper part of the head is dark; the belly of a dingy red. No. 6 resembles the preceding, except that the under surface, instead of being dingy red, is pale reddish white. The *ventral and anal fins* are reddish brown, *margined anteriorly with white*. The pectoral fins are reddish brown, the dorsal fins are brownish black. Both these specimens are marked on the sides with obscure pale-reddish spots." These two fish were what the fishermen called *case char* (Salmo alpinus?), male and female,—yet the pectoral, ventral, and anal fins of the former, and the ventral and anal fins of the latter sex, were conspicuously margined with white, although that character is usually regarded as distinctive of the torgoch or *red char*. Perhaps the fact of the male having the pectorals so margined, while those of the female were of uniform colour, may be regarded as of some importance, as tending to show that the character itself is in some measure variable, and therefore insufficient to constitute a specific distinction.[3] Every angler knows that the under fins of the common trout are frequently margined on one edge with an opake line of milky white.

Although the art of angling is not immediately connect-

---

[1] We understand that Mr Yarrell has obtained what he considers as a second species of char, from Wales, which will be described in an early number of his *British Fishes*. We are as yet, however, uncertain whether he makes out the two common kinds to be identical, and has discovered a new species, or whether his observations merely go to prove that the said kinds (as formerly supposed) are distinct from each other.

[2] The chief feeder or head stream of Windermere is composed of two branches, the Brathay and the Rothay, which meet a short way above the lake, into which they speedily pour their united waters. The Brathay is the left-hand branch (as we ascend from the lake), and draws its sources from the mountain vales of Langdale, reaching Windermere without any resting place,—while the Rothay has previously formed and flowed from two consecutive lakes, Grassmere and Rydal. The char, in ascending from Windermere to spawn, invariably turn to the left, and ascend the Brathay (though to no great distance), and as invariably avoid the lake-descended waters of the Rothay. They also spawn lower down the Lake of Windermere, at the mouth (or a short way upwards) of the stream called Troutbeck, which is also derived from the flow of mountain tributaries, without any lesser or intermediate lake.

[3] The specimens above alluded to are now deposited in the Edinburgh College Museum.

Malacopterygii Abdominales. Salmonidæ.

ed with the science of Ichthyology, it is at the same time evident that the successful practice of that art necessarily illustrates the *food* of fishes, and therefore makes us acquainted with an important portion of their natural history. For this reason we insert the following memoranda, transmitted to us by Mr John Wilson, junior:—"The season for fishing char (with rod and line) in Windermere and Coniston commences about the end of May, and, I should say, is over by the first or second week in July. Trolling with a smallish minnow is by far the most successful mode of angling for this fish. It may, however, be taken with the artificial fly, the green and gray drake being the favourites. I killed three one day in May last with a small red *professor*.[1] A Bowness fisherman on the same day, trolling without intermission from six in the morning till six in the evening, killed *six and twenty*, being the greatest number that has been taken in Windermere, in a single day, by one person, for many years. In Coniston, where this fish is more abundant, I believe it is by no means uncommon to kill three or four dozen in a day. In regard to the size of char in Windermere, I should say they average three to the pound. I never saw one that was a pound. Billy Balmer told me that he once saw one that was a pound and a quarter, and that it was the largest ever taken in Windermere." In relation to the same subject, in a different locality, we may also add the following extract from another hand. "A small red char is found in Loch Achilty, Ross-shire, on the property of Sir George Mackenzie. It takes the fly greedily in warm, still weather, and, what is singular, during all the summer and autumnal months. I have captured eighteen in a forenoon in July,—raising many more. My flies were of various sorts, from a midge to one as large as a sea-trout fly. The water of Loch Achilty is singularly deep and transparent,—the soil is rich and loamy, and contains large quantities of imbedded wood,—black oak especially. It is supplied by numbers of minute streams, but has no visible outlet, being supposed to discharge itself subterraneously. The char found in it average eight or nine inches in length; we, however, caught one much larger. They rise with less velocity than the trout, and on missing the fly, unless injured, will return to the hook. In Strathglass there is a Loch Bruiach, where char are caught of a much larger size, but chiefly with the net,—except in the month of October, when, as our informant, the Rev. Mr Chisholm, told us, they may be taken in the shallows with the rod, but at no other season."[2]

On dissecting the char which we killed last summer in Sutherland, with a view to ascertain their food, we found the stomach usually empty, but the lower part of the intestine filled with green vegetable residuum. This we found to be the remains of the *cases* of aquatic larvæ (*Phryganidæ*), a few of which we discovered in a half digested state in the upper portion of the intestinal canal.

Following the preceding groups, or *Salmones* properly so called, Cuvier has placed the

Genus Osmerus of Artedi. Characterised by two rows of teeth on each palate bone, the vomer with a tuft on the fore part, the branchial membrane with only eight rays, the body without spots, and the ventral fins placed a little more forward than in the true salmon.

The best-known species is the *O. eperlanus*, Arted., *Salmo eperlanus*, Linn.; called *spirlin* in Scotland. It is a small fish of delicate but brilliant colours, clear green on the upper parts, passing into silvery on the sides and belly. It frequents the sandy bays at the mouths of rivers, which during the breeding season it ascends to spawn. It is abundant on the British coasts, and in many parts of Europe, and is taken in immense quantities, being much esteemed for the table.

Genus Mallotus, Cuvier. Characterised by the teeth, which are fine, closely set, and nearly concealed; eight rays to the branchial membrane; the body lengthened and covered with minute scales; the first dorsal and ventral fins placed beyond the middle of the fish, pectoral fins very large and round; the male during the breeding season with the scales of the lateral line furnished with lengthened appendages resembling hairs.

The only species is *M. Groenlandicus*, Cuv.; *S. Groenlandicus*, Bloch; *Capelan*, or *Lodde*. A small fish of from four to seven inches in length, the under jaw longer than the upper; above of a greenish gray, changing to whitish below; and remarkable for the structure of the scales on the lateral line, and the size of the pectoral fins. Abundant in the Arctic Seas, where it is taken in immense profusion when approaching the coasts to spawn, and is used as the principal bait for cod. A few are cured and brought to this country in barrels, where they are sold, and used as a *relish by the curious in wines*.

Genus Thymallus, Cuvier; *grayling*. Has been separated from the Guiniads, principally on account of the small scaling, and large dorsal fin. The species approach nearer in form, colour, habits, and food, to the trouts. They have the mouth with sides, that is, but slightly cleft, the teeth very fine, the body spotted, the branchial membrane with seven or eight rays. The stomach is very muscular. They inhabit rivers, and feed on aquatic insects, &c. England produces a beautiful species, commonly called the grayling, or

Thymallus thymus,[3] Salvianus. The grayling delights in clear rapid streams, and is found in many of those bearing that character in the more hilly or mountainous parts of England, particularly in Shropshire, Yorkshire, and Derbyshire,—reaching as far north as some of the tributaries of the Tyne in Northumberland. The European range of this fish seems extensive, if all the authors are correct in their designation. According to the *Flora Lapponica*, it is common in Lapland, and the viscera are there used instead of rennet, with the milk of the reindeer. It is also found in Siberia, in Prussia, and Pomerania. It is a very beautiful fish, above of a dusky bluish green, changing to a fine silvery gray. The lower edges of the scales are dusky, which gives the appearance of dark streaks running along the fish. The most marked feature is the dorsal fin, of very large size, and darkly spotted between the rays, in the form of transverse bands. The ordinary size is from a foot to sixteen inches in length, but instances of one or two from four to five pounds are recorded. By some authors the grayling is said to be a migratory fish, passing the winter in the open sea, and the summer in the fresh waters. This may, however, be the habit of the fish in some countries only, as in certain of the English rivers they seem to remain during the winter. This species, as far as we know, appears to be the sole example of the form in Europe; and it is only seen again in North America, in a very beautiful fish, the

Thymallus signifer, Cuv.; *Coregonus signifer*, Richards. This grayling was met with by the expedition under Captain Franklin, in the strong rapids and clear rivers to the northward of Great Slave Lake, where it rose eagerly at artificial flies, and afforded good sport from its

[1] A noted fly, so named in honour of the Professor of Moral Philosophy in the University of Edinburgh,—a gentleman who is said to conjoin with various other accomplishments, considerable skill in angling.

[2] From the manuscript of Mr Thomas Tod Stoddart, an ingenious angler, of the Scotch bar.

[3] So named from its supposed scent or flavour resembling thyme.

powerful motions in the water. Dr Richardson describes its sides as tinged with lavender purple, mixed with bluish gray, without streaks; the belly blackish gray, with several irregular white blotches; and there are five or six longitudinal rows of uniform quadrangular spots of Prussian blue on the anterior part of the body. There is a large blue mark underneath the lower jaw on each side. The dorsal fin, which forms a prominent feature in the fish, is of a blackish-gray colour, with some lighter blotches. Superiorly it has a narrow margin of light lake-red, and posteriorly it is beautifully ornamented with spots of Berlin blue. The ventrals are streaked with red, and with whitish lines in the direction of their rays. The scales are moderately large, and have no great lustre; their exterior margins are rotund and entire, or very slightly undulated, those on the anterior part of the belly being much smaller than the others. Of the fins the dorsal is the most extraordinary, being, according to Dr Richardson, "probably by far the largest in this genus." Its colours, as above mentioned, are beautiful, and, with its great size, form the chief ornament of the fish. It contains twenty-four rays; the first two or three are small; but the others increasing rapidly in height, as their origin is more posterior, become more and more branched, and cause the fin to play loosely like a flag over the posterior part of the body; the insertion of the fin occupies about one third of the length of the body, and the extremity of the posterior ray, which is five inches long, reaches as far as the adipose fin.[1] Specimens were taken sixteen inches in length. Another American grayling, found in the same northern localities, is the *Thymallus thymalloides*, Cuv.; *Coregonus thymalloides*, Richard. Resembles *Th. signifer*, but differs remarkably in the size of the dorsal fin. The body is compressed, and of a bluish gray, with purple reflections when moved in the light. The dorsal fin contains from twenty-two to thirty-four rays; but the posterior ones do not branch out in the same manner, and scarcely exceed the others in height; hence the fin has a very different aspect. It is about one inch high, has a dark bluish-gray colour, with several rows of spots, having purple centres and light-red borders. The usual length is eight inches.[2]

Genus Coregonus, Artedi. Distinguished from the last by the still finer teeth, larger scaling, and small dorsal fin; live in shoals in lakes or still waters, and only approach the edges during spawning time. Of delicate structure; feed much on entomostraca, and aquatic insects and their larvæ. Flesh white and delicate. The best-known British species is the Guiniad, or

Cor. lavaretus, *Salmo lavaretus*, Linn. Frequent in the lakes of Cumberland and Westmoreland, and also found in some of the Scotch lochs,—for example, Loch Lomond, where, as in the north of England, it is termed the *schelky*. According to the best authorities, it likewise occurs in those of Alpine and Northern Europe. It does not reach a very large size; the average may be stated from nine inches to a foot in length. The colours chaste and delicate, of a greenish gray above, changing to whitish, with a silvery lustre. The scales are of considerable size, and, when examined narrowly, are seen to be covered with minute black dots. It is used for the table, but is not so delicate as our other British species. It is known under the name of *fresh-water herring* in most of its localities.

Cor. marænula, found in the Swiss lakes and some other parts of the Continent of Europe, is a small species, of nearly the same colours as the last. This fish was supposed to be found in some parts of Britain, and the *vendace* of the Lochmaben lochs was thought referrible to it. When Scotch specimens, however, were shown to Mons. Agassiz during the autumn of 1834, he considered them distinct from the species known to the continental Ichthyologists as *C. marænula*, and the title of *C. Willughbii* was suggested for the Scottish kind. Continental specimens of *C. marænula* have not yet been received by us, and the distinctions, therefore, cannot at present be detailed. The *vendace* of Lochmaben, whatever scientific name it may ultimately receive, or whether it may be identical or not with the species inhabiting the lakes of Continental Europe, may be described as an interesting example of the genus. It is one of the most elegant, though of a small size, reaching from four to ten inches in length. The head is of an angular shape, and small compared with the size and depth of the body. The crown of the head is very transparent, and the form of the brain, which is heart-shaped, is seen through the integuments. This peculiarity is one of the first things pointed out to the stranger naturalist who visits Lochmaben to see this species. The eye is large and brilliant; the body rises gracefully to the back fin, and recedes with a gradual line to the tail; the under line is nearly straight from the gills to the ventral fin. The upper parts are of a delicate greenish brown, shading gradually into a clear silvery white; the dorsal fin greenish brown, the anterior edge much lengthened and pointed; the lower fins all bluish white; the tail much forked. They spawn about the commencement of November. The roe is minute and abundant, and of a bright orange colour. The flesh is white and rich, and highly prized as food; but as it requires almost to be *eaten on the spot*, it is not useful as a market commodity when transmitted to any considerable distance. The lochs of Lochmaben are the only authentic British habitat for this species.

Several other species inhabit the Swiss lakes, and are known chiefly from the works of the continental Ichthyologists, particularly M. Jurine, who has devoted a paper to the fishes of the Lake of Geneva. He there describes *C. fera* and *hyemalis* (the latter so named from its appearing only in winter); and Baron Cuvier notices a third from the Lake Neufchatel, under the title of *C. palæa*. In America several species are found in the lakes and rivers. The *white fish* of Dr Richardson seems to belong to the genus. It is the *C. albus* of Lesueur, and is called by the Cree Indians *Attihhawmegh*, a name corrupted to *Tittameg* by the traders. This fish attains a weight of from three (the ordinary size) to twenty pounds. It abounds in every lake and river, and is much esteemed as food, in many parts forming the sole article of diet for years together, without producing satiety. The stomach is of great thickness, generally filled with earth mixed with slender roots, and small white worms. It spawns in October. Another species is *C. quadrilateralis*, Richardson, of which the colour of the upper parts is intermediate between honey yellow and wood brown; the scales with a thin border of blackish gray round their exterior margins; the belly white, with a pearly lustre; the eye moderately large, the iris with a silvery hue; the mouth without teeth; the fins are yellowish; the adipose fin attached for its whole length. The stomach not thickened. The food small insects. Inhabits the Arctic Sea, and the small rivers about Fort Enterprise. The average size is about fifteen inches in length.

Under this division also appears to rank the *Inconnu* of Mackenzie and the Canadian Voyagers, although it is placed by Dr Richardson in the genus *Salmo*, under the name of *S. Mackenzii*. We therefore here record it as

---

[1] Richardson, in the *Appendix* to Franklin's *Journey to the Polar Sea*, p. 711.

[2] *Ibid.* p. 714.

Malcopterygii Abdominales. Salmonidæ.

the *Coregonus Mackenzii*. The colour of the back and sides changeable from bluish to greenish gray, according as it is moved in the light. The belly bluish white; the scales sub-orbicular, four lines in diameter, and possessing much pearly lustre. From the form of the body, the size of the scales, the fineness of the teeth, and their distribution, this fish evidently belongs to the genus *Coregonus*. It reaches a weight of thirty or forty pounds. The flesh is white but agreeable. It is found in Mackenzie's River, and the lakes and streams which flow into it; also in Salt River, which, however, is its most southerly limit.[1]

GENUS ARGENTINA, Linn. The mouth small, depressed horizontally; no teeth on the jaws, but with a small tuft on the vomer, and having the tongue with teeth rather strong and hooked, as in the trouts. Six rays to the branchial membranes. The internal structure as in the trouts. The genus is composed of a single species, the

Arg. sphyræna, Linn. Found in the Mediterranean sea, and remarkable for the thickened coats of the swimming bladder, which, as well as the scales, is plentifully charged with that silvery secretion used in the manufacture of "*l'essence d'orient*," an article employed in the formation and lustre of false pearls. For this purpose the species is fished in great numbers along the coast of Tuscany. It is a small fish, scarcely exceeding four or five inches in length, of delicate tints,—the integuments being transparent, and giving a clear brilliancy to the colours. The upper parts are grayish, the sides and lower surface of a brilliant silvery lustre.

Following this fish, Cuvier adopts the genus CHARACINUS of Artedi, as a group to contain all the species of the Linnæan *Salmones*, which have only four or five rays to the branchial membrane, but as the form, toothing, &c. vary in most of these fishes, he has thought it necessary to subdivide them into subordinate genera. It is remarkable that many of them have the cæcal or pancreatic appendages, and at the same time the narrowing or girth of the air-bladder, which is seen in many of the Cyprini. The first subdivision is

GENUS CURIMATA, Cuv. In form the species resemble *Thymallus*. The teeth are, however, variable, and the divisions of this group may yet require examination. The number of branchial rays not exceeding five, must be remembered; some of the species, with the exception of that distinction, approaching very nearly to the genus just named. They inhabit the rivers of South America. As an example may be noted a new species, the *Curimata Gilbert* of Quoy and Gaimard. This fish somewhat resembles a small *Cyprinus*, but is distinguished, even on a superficial view, by the presence of the adipose fin. The scales are rather large in proportion; the upper parts are bluish gray, changing into silvery; the fins yellowish; the body appears spotted, or rather blotched, with indistinct dark markings, conspicuous only when placed in particular lights. This species was discovered in the fresh waters of Brazil, near the river Macaca, and appeared to prefer those places which were of a marshy character.

GENUS ANASTOMUS, Cuv. Characterised by combining with the form of the graylings a mouth cleft somewhat vertically, and furnished with fine teeth. It contains a single species, a native (it is said) both of South America and India, the *Salmo anastomus*, Linn. Is it not likely that two species are confounded here?

GENUS GASTEROPELECUS, Bloch. With the mouth placed vertically as in the last, but with the belly compressed. The ventral fins very small, and placed far back. The first dorsal fin placed above the anal, which is very long. Conical teeth in the upper jaw, in the lower sharp and cutting.

Gast. sternicla, Bloch, is a very small species, scarcely two inches in length, which inhabits the waters of Surinam. Its form is very much compressed, and sharply carinated beneath; above bluish gray; beneath silvery.[2] The fins gray, ventrals extremely minute, the anal extending nearly from them to the tail; the tail much forked.[3]

GENUS PIABUCUS, Margrave? Characterised by a lengthened form; a small head, with the mouth deeply cleft and armed with strong teeth. The body compressed; the belly carinated, but smooth; the anal fin much extended. The species inhabit the rivers of South America, and are carnivorous and voracious.

P. bimaculatus. About four inches in length by about two in breadth. Above brownish, lower parts silvery; fins pale yellow; on each side of the body beyond the gills an oval spot of black, with a similar one at the base of the tail. Inhabits the rivers of Surinam, and is esteemed as food.[4]

GENUS SERRASALMUS, Lacépède. The body compressed; the belly carinated, and toothed or serrated on its lower margin; the teeth triangular and cutting; some species with a concealed spine before the first dorsal fin.

Ser. rhomboides, Bloch. Above of a dusky red, marked with a few small scattered dusky spots; sides and belly silvery, the latter strongly carinated and serrated by a series of aculeated processes. The fins yellowish; tail terminated by a black border. Found in the rivers of Surinam, where it reaches a considerable size; feeds on fish and *water-fowl!* Two other species, *G. aureus* and *nigricans*, are figured in the work of Spix.

GENUS TETRAGONOPTERUS. This group was formed by Artedi, and after being thrown out by Ichthyologists, was re-established by Cuvier as a sub-genus. The form continues compressed, the anal fin much extended, and the teeth sharp and cutting; but there are two rows of teeth on the upper jaw, and the belly is neither carinated nor serrated, as in the preceding.

GENUS CHALCEUS, Cuvier. Characterised by the same form of the mouth, and the same cutting teeth, as the preceding fishes; but the body is of an oblong form, and neither carinated nor serrated beneath. The maxillary bones have three small round teeth. Inhabit South America. The species are *C. macrolepidotus*, Cuv., and *C. angulatus*. Spix.

GENUS MYLETES, Cuvier. Characterised by the singular form of the teeth, in the shape of a triangular prism, short, rounded at the corners, and with the upper surface so hollowed by mastication, that the three angles form three projecting points. The mouth small, with two rows of teeth on the inter-maxillary bones. None on the maxillaries. The under jaw with a single row of teeth. The form elevated; a spine before the vertical fins. The belly carinated and serrated. Inhabit America and Africa. Some of the species attain to a large size, and have the flesh well flavoured.

M. Hasselquistii, Cuv., *Salmo dentex*, Hasselquist, is found in the Nile. It is a fish of a lengthened form, with the dorsal fin occupying the position which corresponds to the space between the ventral and anal fins. The teeth are very strong. The colours above are brownish, with three or four indistinct longitudinal lines upon the sides; the under parts silvery.[5] *M. paco* is an American species.

[2] Schneider. [3] Shaw. [4] Schneider, Shaw. [5] Schneider.

Malacopterygii Abdominales. Salmonidæ.

Genus Hydrocyon, Cuvier. Extremity of the muzzle formed by the inter-maxillary bones; the maxillaries commencing near or before the eyes, and completing the upper jaw. The tongue and vomer always smooth, but there are conical teeth on both jaws. A large sub-orbitary bone, thin and bare as the opercle, covers the cheek.

Certain species have a close row of small teeth on the maxillary and palatine bones, the first dorsal fin corresponding to the space between the ventral and anal fins. They are of agreeable taste, and inhabit the rivers of the torrid zone. To this group belongs the *Hyd. falcatus*, Quoy and Gaim. Above of a violet tint, beneath pale, but tinted generally with a shade of silvery. A silvery band extends the whole length of the body from the opercle to the tail, and at each extremity is marked with a dark spot. The fins gray at the base, and brown at the extremity. The eyes of a golden red. The scales small and deciduous. The specimens brought by Freycinet were from five to six inches in length. They were taken in Brazil.

Other species have a double row of teeth on the inter-maxillaries and lower jaw, a simple row on the maxillaries, and none on the palatine bones. The first dorsal fin is placed above the ventrals. A Brazilian species, *H. brevidens*, Cuv., exemplifies this minor group.

Others again have only a simple row of teeth on the maxillaries and lower jaw, but the teeth are alternately small and very large, especially the two second from below, which pass through hollows of the upper jaw when the mouth is shut. The lateral line is composed of scales of a larger size, and the dorsal fin is so placed as to correspond to the interval between the ventral and anal fins. *H. scomberoides*, Cuv. or *Cynodon vulpanus*, Spix, is an example of this peculiar form.

Another form has the muzzle pointed, the maxillary bones very sharp, and the inter-maxillaries and lower jaw furnished with a single row of very close, small teeth; the body covered with strong scales. A Brazilian species, *H. lucius*, Cuv. affords a characteristic example.

A fifth form has teeth only on the inter-maxillaries and lower jaw, and these few in number, but strong and pointed. The first dorsal fin is placed above the ventrals. A single species from the Nile, the *Characinus dentex* of Geof. (*Pois. d'Egypte*), presents the sole example of this limited group.

Genus Citharinus, Cuvier. Characterised by their depressed mouth, the upper edge formed entirely by the inter-maxillary bones. The maxillaries small and without teeth; the tongue and palate smooth; the adipose fin covered with scales, together with the greater part of the tail. The species inhabit the waters of Africa.

Some have the upper jaw only furnished with very fine teeth; the body elevated as in *Serrasalmus*, but without the carinated or serrated abdomen.

Salmo cyprinoides exemplifies this division of the genus. Others have on both jaws a number of teeth, thickly placed in several rows. These fish are more lengthened in their form, and appear to lead to the next genus. *Salmo Ægypticus*, Linn. serves as an illustration.

Genus Saurus, Cuvier.[1] Distinguished by its lengthened and cylindrical form, and by the large scales, which cover also the cheeks and opercles. The edges of the upper jaws are formed entirely by the inter-maxillaries; and on each, as well as on the palatine bones and the tongue, are numerous pointed teeth, which are wanting on the vomer. The first dorsal fin is placed much posterior to the ventrals, which are large. The interior structure resembles that of the trouts. They are very voracious.

This form is illustrated by the *Salmo saurus* of Bloch and Linn., a native of the Mediterranean; above of a greenish blue, varied with numerous narrow undulated transverse bands, reaching as far as the lateral line, which is itself bounded beneath by a continued stripe of brown; abdomen silvery. The fins pale, the pectorals crossed with a few brown bars.[2]

S. variegatus, Lacépède, Quoy, and Gaimard. The jaws, tongue, and palate with formidable sharp teeth. The upper parts of a dull gray, banded transversely with eight or nine brown bands, broad and irregular when ceasing at the centre of the fish. The under parts tinted with rose colour. The eye red and brilliant. In this fish the second dorsal fin is so small as not easily to be perceived. Found in the neighbourhood of the Sandwich Isles.[3]

S. gracilis, Quoy and Gaimard. A small species, reaching only about four inches and a half in length. The colours are unobtrusive, being a dull gray blotched with irregular blackish spots, most defined on the sides and towards the tail. All the fins are covered with brownish specks, which on the pectorals are so disposed as to form three transverse bands. This fish was also found in the neighbourhood of the Sandwich Isles.[4]

Genus Scopeles, Cuvier. Mouth and opening of the gills wide; the jaws furnished with very fine teeth; the upper jaw formed entirely by the inter-maxillaries; the tongue and palate smooth; the branchial rays from nine to ten; the adipose fin small, but having a trace of bony rays. The species are small in size, and live in shoals. They are found in the Mediterranean Sea. The *Sc. Humboldtii* of Risso offers a characteristic example.

Genus Aulopus, Cuvier. In this form the characters of the *Cod* or *Gadi*, and *Salmones*, are united. The mouth is widely cleft, the inter-maxillary bones, which form the border of the upper jaw, are furnished, together with the palatine bones, the vomer, and the lower jaw, with a narrow stripe of teeth *en carde*. The maxillary bones are longer, and without teeth. The ventral fins are placed almost under the pectoral fins, and have the outer rays strong, and simply forked. The body, cheeks, and opercles, are covered with large ciliated scales. *Salmo filamentosus* of Bloch illustrates *Aulopus*.

Genus Sternoptyx, Herman. These curious fish have by Cuvier been placed under the above title at the conclusion of his Salmonidæ. They embrace two forms, which, he thinks, will eventually be converted into sub-genera. They are of small size, the body high, and very compressed; the mouth directed upwards. The humeral bones form on the fore-part a sharp crest or ridge, terminated below by a small spine. The pelvic bones form another and similar crest, also terminated by a small spine placed before the ventral fins, which are so minute as to have escaped the observation of the first observer. On each side of the last ridge there is a row of small hollows, which has been regarded as a fold of the sternum, and has suggested the name of *Sternoptyx*. Before the dorsal fin there is a bag or membranous ridge, and behind this fin there is a small membranous projection, which is thought to represent the adipose fin of the true Salmones.

The first form of this genus has very fine teeth, with five rays to the branchial membrane, and is represented by *St. Hermannii*. The second has the teeth hooked, and nine rays to the branchial membrane. *St. Olfersii* exhibits the only known example. Both species are from the warmer parts of the Atlantic Ocean.

---

[1] Named from their lengthened Saurian or lizard-like form, and distinguished from the other groups derived by Cuvier from the genus *Characinus* of Artedi, by the branchial rays ranging from eight to fifteen in number.

Malacopterygii Abdominales. Clupidæ.

FAMILY V.—CLUPIDÆ.

Fishes allied to herrings are easily recognised by their having no adipose fins; their upper jaw is formed as in trouts,—in the middle by inter-maxillary bones without pedicles, and on the sides by the maxillary bones; their body is always very scaly. The majority of the species possess a swimming bladder and numerous cæca. Those which ascend rivers are comparatively few in number.

The great genus CLUPEA of Linnæus may be known by two well-marked characters; 1*st*, by the narrow and short inter-maxillary bones, which constitute only a small portion of the upper jaw, the sides of which are completed by the maxillaries in such a way that the lateral parts only are protractile; and, 2*d*, by the compressed and sharp inferior edge of the body, upon which the scales project like the teeth of a saw. Besides, the maxillaries are divided into three pieces. The branchial openings are very much cleft; and hence these fishes speedily die when removed from their native element.

Their branchial arches are furnished on the side next the mouth with pectiniform dentations. The stomach has the form of an elongated pouch; the swimming bladder is long and pointed, and in some species sends forwards two long and small processes, which communicate with the internal ear in a remarkable manner. Their cæca are numerous. Of all fishes, these have the most numerous and the finest bones.

GENUS CLUPEA, Cuv. Herrings, *properly so called.* The maxillary bones arched anteriorly, and longitudinally divisible into several pieces; the opening of the mouth of moderate size; the upper lip not emarginate.

C. harengus, Linn. The common herring; *le Hareng*, Fr.; *der Häring*, Ger. This well-known fish has visible teeth in both its jaws; the carina of the belly is but slightly marked; the sub-opercle is rounded; there are veins on the sub-orbital, pre-opercle, and upper part of the opercle. The attachment of the ventral fins corresponds to the middle of the dorsal; the head is one fifth of the length of the whole fish, and by carrying backwards from the first dorsal fin the distance of that organ from the snout, we arrive at the middle of the caudal. The anal fin has sixteen rays.

The investigation of the habits of this fish has not received that attention which its importance as an article of food to the inhabitants of this country demands; and there are several circumstances respecting its economy which still require farther examination. It is generally believed that the herring inhabits in winter the depths of the Arctic Ocean, or other seas in northern latitudes, and that during the rest of the year it makes migrations southwards. In summer and autumn they appear on the north and west coasts of Europe in immense shoals, and about the same season they arrive at some parts of the coast of America and Asia. It has been supposed that those coming from the north divide into two detachments, one of which proceeds along Newfoundland to America, the other along Norway to the south of Europe, and that one subdivision of this second detachment goes up the Baltic, while the other proceeds along Great Britain, Ireland, Germany, and France, as far as the western coast of Spain.

This is the description of the annual migrations of the herring given by Pennant; but some doubts have been entertained as to its accuracy, from the circumstances, 1*st*, that while in some places the herrings do not make their appearance for years, in others they are taken in abundance all the year round; and, 2*d*, that they have never been observed on their return northwards. Other naturalists suppose that they come merely from the deep into shallow water during the spawning season, and that in so doing they do not make any very lengthened journeys. In truth, we are not as yet furnished with sufficient data to decide the question; but, in the mean time, we do not feel inclined entirely to reject the generally received opinion, that the herrings migrate from north to south in summer and autumn.

Malacopterygii Abdominales. Clupidæ.

In migrating, the herrings proceed in vast troops,—so great, indeed, that the sea is sometimes covered with them for miles, and that they have even been known to be stranded or crushed in immense quantities in confined bays, or when thrown by the wind or by currents upon the shore. The shoals are said to be generally preceded, sometimes for days, by one or two males. The largest generally go first, to act in some measure as guides; and, as they proceed onwards, immense numbers fall an easy and unresisting prey to rapacious birds, or to their own not less rapacious kindred of the sea.

It is generally believed that the herrings captured far north are larger, fatter, and of a better quality, than those of the south; and for this reason, in the month of July, our fishermen go out to meet the shoals as far as Orkney and Shetland. The greatest number are taken on the coasts of Norway and Sweden, in the first of which countries it is said that about 400 millions are taken in one year, and sometimes twenty millions in a single fishery. The inhabitants in the neighbourhood of Gothenburg, in Sweden, take as many as 700 millions in a year. Herrings are fished also in great quantity in this country, Germany, France, Holland, the United States, and Kamtschatka.

The average size of the herring is stated to be about ten inches. According to Dr Knox, the females are considerably larger than the males,—the largest female he found on the east coast of Scotland measuring eleven inches, the largest male nine inches and a half. It does not appear to be precisely known at what age they attain their full size.

Considerable doubt has at all times prevailed regarding the food of the herring. They were generally stated to live on small crabs and fishes, and on a minute crustaceous animal named by Fabricius *Astacus harengum.* But this was chiefly matter of supposition, for most practical fishermen described the stomach of the fish when in good state as quite empty, or, at most, as containing a little brownish mucus; and it has appeared difficult to reconcile the fact, that it is when the stomach appears thus empty that the fish is in its best condition, viz. fullest, with the finest flavour, and most capable of keeping,—with the notion, that when it appears upon our coasts it has quitted its natural feeding ground, and has been longer and longer in a state of starvation the more southern the latitude in which it is found. Dr Knox's interesting observation, that the principal food of the salmon and vendace consisted of minute crustaceous animals, led him to examine carefully with the microscope the brownish matter contained in the alleged empty stomachs of the herring; and he then formed the opinion, that this matter consisted of the debris of a very minute entomostracous animal.[1]

It is well known that the herrings caught upon the east coast of Scotland are much inferior to those taken on the west coast, and more particularly to those of Loch Fine, and other lochs of Argyleshire. Dr Knox states that the herrings taken near the Firth of Forth in July are foul, or are engaged in spawning, while those of the west coast, in the same season, have the organs of reproduction very slightly developed; and he conjectures that that species of crustaceous animal which forms their appropriate and most favourite food may exist abundantly in the bays on the west coast of Scotland, and either not at all, or not in

[1] It is figured in the *Edin. Phil. Trans.* vol. xii. pl. x.

sufficient quantities, along our eastern coasts. It appears to be chiefly after these fishes have been absent for some time from their proper feeding places that they eat marine worms and small fishes; and when so feeding they lose much of their flavour, and run rapidly into putrefaction after being captured. The time of spawning seems to vary considerably, both in the same and in different districts; so that we may have spring, summer, and autumn herrings, as we know they have in some parts of the Baltic. During the spawning season they are seen to rub their bellies against the rocks or sand. As many as 68,606 eggs have been counted in one female. The young do not accompany the larger herrings in their migrations.

Of the genus *Clupea*, Cuvier makes four other species besides the common herring, viz. the *sprat*, *white-bait*, *pilchard*, and *sardine*. Of these we shall now give a short account.

Clupea sprattus, Bl. The sprat, mellet (*Esprot*, *Haranguet*, Fr.), bears a very close resemblance in form to the herring, but does not attain the same size. The number of its vertebræ is forty-eight, and the dorsal fin is placed farther back than in the herring. It has no veins on the opercle; a gilded band runs along the sides in the spawning season. This fish is eaten in considerable quantity in this country, both in the fresh and salted condition. It appears in the Thames from November to March.

Clupea latulus, Cuv. White-bait (*Blanquette*, Fr.; *die Breitling*, Germ.) has the body more compressed, and the belly sharper, than the herring. The length of its head, and height of its body, are each one fourth of the whole length of the fish. The dorsal fin is placed farther forwards, the anal is longer and situate nearer the caudal fin, than in the herring.

Considerable difference of opinion formerly existed among ichthyological writers as to the exact specific nature of the white-bait. Pennant and Shaw considered it as allied to the bleak, *Cyprinus alburnus*. Turton, Donovan, and Fleming, regard it as the young of the shad *Clupea alosa*, an opinion which was generally received as correct, until Mr Yarrell in 1828 ascertained that the number of vertebræ in the white-bait is invariably fifty-six, and in the shad only fifty-five; and he is thus supposed to have demonstrated that the well-known *white-bait* ought to be regarded as a species distinct from every other. It is a very small fish, seldom exceeding four inches in length. It is of a very brilliant silvery colour, and has a black spot on the end of the snout. The flavour of the white-bait is considered as particularly delicate, and great numbers are eaten by the Londoners in the month of July, at which time innumerable quantities make their appearance in the Thames.

Clupea pilchardus, Bl. The pilchard (*le Célan*, Fr.) nearly equals the herring in size, and bears a considerable resemblance to it in form. The sub-opercle is quadrangular, the pre-opercle and opercle striated; the head proportionally shorter than in the herring, and the dorsal fin placed farther forwards. The ventral fins begin as it were under the end of the dorsal; the anal consists of eighteen rays; and on each side of the caudal two scales longer than the rest project. The habits of this fish seem to be nearly the same as those of the herring. It is believed, like it, to reside in winter and spring in the northern seas, and to proceed southwards in the beginning of summer. It is fished in enormous quantities off the coast of Cornwall for the purpose of salting and exporting to the Mediterranean, especially to Naples. It appears there in July. Its flavour is considered by some as even superior to that of the herring.

Clupea sardina, Cuv. The sardine, which is esteemed for the extreme delicacy of its flavour, differs only in size from the pilchard. Numbers are taken off the coast of Brittany, and also in the Mediterranean.

GENUS ALOSA, Cuv. This genus is distinguished from the herrings properly so called, by an emargination in the upper jaw; its other characters seem in all respects the same as those of the pilchard and sardine.

Alosa vulgaris, Cuv.; *Clupea alosa*, Linn. Plate CCCV. fig. 2. The shad is distinguished by the absence of sensible teeth, and by an irregular black spot behind the gills. This fish is much larger than the herring, attaining sometimes to the length of three feet. It is also of a much flatter shape; its tail is much forked; and on each side of the lower margin of the belly the scales are very large. It is a native of the Mediterranean, as well as of the North Atlantic and Caspian Seas. According to Pennant, the best in this country are found in the Severn. The shad ascends rivers in spring and the beginning of summer, and it is then highly esteemed; but it is of a dry and disagreeable flavour when taken at sea. The Russians believe that the shad has deleterious properties. The Arabs smoke-dry it. This species lives chiefly on vermes, insects, and small fishes; and Dr Fleming informs us that he has taken small herrings from its stomach. The number ascending rivers varies very much in different years.

Alosa finta; *Clupea finta*, Lacép. The *veuth* of the Flemish is more elongated than the shad, and has well-marked teeth in both jaws; there are five or six black spots along the flanks. It is found as far south as the Nile. Its taste is very inferior.

GENUS CHATOESSUS, Cuv. The chatoessi are true herrings, with the last dorsal ray prolonged into a filament. Some have the jaws equal and the snout not prominent, and a small mouth devoid of teeth. In others the snout is more prominent than the jaws; an equally small mouth with the preceding; the upper combs of the first pair of gills unite together so as to form a very singular pennated point beneath the palate.

At the end of the true herrings Cuvier has placed some foreign genera which resemble them in their sharp and dentated belly.

GENUS ODONTOGNATHUS, Lacép.; *Gnathobolus*, Schn. Has the body much compressed, and very sharp dentations along the whole of the belly; the anal fin long, and projecting little; the dorsal so brittle as to be almost always destroyed; six rays in the branchial covers. The maxillary bone is somewhat prolonged into a point, and is armed with small teeth directed forwards. There are no ventral fins.

One species only is known. It comes from Cayenne; resembles a small sardine, and is called by Lacépède the *Odontognathe Aiguillonné*.

GENUS PRISTIGASTER, Cuv. Has the head and teeth similar to those of the herrings; four rays to the gill-covers, and no ventral fins; the belly much compressed, its lower edge arched, and sharply dentated.

The *Prist. tardoore* and *Prist. cayanus* are mentioned by Cuvier as known species existing in both oceans.

GENUS NOTOPTERUS, Lacép. Was placed among the *Gymnoti* for some time, on account of a resemblance occasioned by the extreme length of the anal fin. The species have scaly cheeks and opercles; the sub-orbitals, lower part of the pre-opercles, the inter-opercles, the two crests of the lower jaw, and the keel of the belly, dentated; there are fine teeth in both palates and jaws, and strongly hooked teeth on the tongue. The branchiostegous membrane has only one strong osseous ray. There are two very small ventral fins, followed by an anal, which occupies three fourths of the whole length of the fish, and united as in the gymnoti to the caudal fin. A small dorsal fin with soft rays is placed opposite to the middle of the caudal.

One species only is known, inhabiting the fresh-water ponds of the East Indies.

Malacopterygii Abdominales. Clupidæ.

Genus Engraulis, Cuv. The *Anchovies* differ considerably from the true herrings in having the mouth cleft far behind the eyes; the gills more open, with twelve or a still greater number of rays; the maxillaries straight and elongated, and there projects in front of the mouth a small pointed muzzle, under which are fixed very small intermaxillaries.

The best known have not the sharp-edged belly; their anal fin is short, and the dorsal is placed opposite to the ventrals.

Clupea encrasicolus, Linn. The common anchovy (*l'Anchois*, Fr.) has the back of a bluish-brown colour, the belly silvery. It measures from four to seven inches long. The anchovy formed one ingredient of the *garum*, a favourite sauce of the Romans; and when pickled it is much prized at the present day. It is fished in greatest quantity in the Mediterranean, but is found as far north as the coast of Holland. It lays its spawn near the shore, from December to March, at which time it is supposed to leave the deep sea and approach the coasts. *Engraulis meletta*, Cuv., an inhabitant of the Mediterranean, is smaller than the common anchovy. Among some remarkable American species of this genus, the *Eng. edentulus* is without teeth. Others, as the *Clup. atherinoides*, *Clup. telara*, and *Clup. phasa*, have the body compressed, and its lower edge serrated.

Genus Thryssa, Cuv. Differs from the last-mentioned anchovies only in the great prolongation of the maxillaries. The species occur in the East Indies.

Genus Megalops, Lacép. Differs from the herrings in having the belly blunt, and the body not compressed. The jaws and palatine bones are covered with small, even, sharp teeth; there are from twenty-two to twenty-four rays in the gill-covers; and the last ray of the dorsal fin, as also often that of the anal, is prolonged into a filament, as in *Chatoessus*.

One species is found in America, the Savalle or Apalike (*Clup. cyprinoides*, Bl.), which attains the enormous length of twelve feet; it has fifteen dorsal rays. Another Indian species, *Megalope filamenteux* of Lacép., has been confounded by Russel with the preceding, under the name of *Apalike*. Its dorsal fin has seventeen rays.

Genus Elops, Linn. Is very similar in structure to *Megalops*, but wants the elongated filament of the dorsal fin. It has thirty or more rays in the branchiostegous membrane; a flat spine on the upper and lower edge of the caudal fin. The species are found in both hemispheres.

Elops saurus is described by Sir Hans Sloane as belonging to America. According to Cuvier, the *Argentina machnata*, Forsk., *Mugil salmoneus*, Forsk., the *Tinagow*, Russ., *Synode chinois*, Lac., *Mugil appendiculatus*, Bosc, the *Pounder*, Sloane, and the *Argentina Carolina*, Linn., are all the same as *Elops saurus*, while the *Saurus maximus*, usually confounded with it, belongs to a different genus.

Genus Butirinus, Commerson. Muzzle prominent like that of the anchovies, and the mouth slightly cleft; twelve or thirteen rays on the branchiostegous membrane; close and even teeth on the jaws; and (a peculiar character) the tongue, vomer, and palatines closely paved with rounded teeth. These fishes are described under various names by different authors.

The *Elopes* and *Butirini* are found in both oceans. They are pretty, silvery-looking fishes, and make excellent soup.

Genus Chirocentrus, Cuv. Have the jaws formed like those of the herrings; both maxillaries and inter-maxillaries furnished with strong conical teeth, two of which above and all below are very long. The tongue and branchial arches are bristled with teeth like a comb, but there are none on the vomer or palatines. Their gill-covers have seven or eight rays, of which the external are very broad. Above and below each pectoral fin is a long, pointed, membranous scale, and the rays of those fins are very hard. The body is elongated, compressed, and sharp beneath, but not serrated. The ventral fins are very small, and the dorsal shorter than the anal, opposite to which it is placed. The stomach forms a long, narrow, and pointed sac, the pylorus being near the cardia; no cæca; the swimming bladder long and narrow.

One species only is known, of a silvery hue, and from the Indian Ocean. It is the *Esoce chirocentre*, Lac., *Clup. dentex*, Schn. and Forsk., *Clup. dorab*, Gmel., *Wallach*, Russ., and probably also the *Parring* or *Chnees* of the Moluccas.

Genus Hyodon, Lesueur. Possesses the general form of the herrings, and their sharp belly, but that part is not serrated. The dorsal fin is placed opposite to the anal; the gill-covers have eight or nine rays; hooked teeth on the vomer; palatines and tongue as in trouts.

Those which are known live in the fresh waters of North America.

Genus Erythrinus, Gronov. A range of conical teeth in each jaw, some of which in front are longer than the rest; the palatines are covered with close even teeth. The gill-covers have five broad rays; the head is without scales; and the cheeks covered by hard sub-orbitals. The body long, little compressed, covered with large scales like those of the carp. The dorsal fin is placed above the ventrals. The stomach forms a broad sac, and there are numerous small cæca. The swimming bladder is very large.

We may mention as a characteristic species the *Esox Malabaricus* of Bloch.

These fishes inhabit the fresh waters of warm climates. Their flesh is agreeable.

Genus Amia, Linn. Similar to the preceding in many respects, but with twelve rays in the gill-covers. Below the lower jaw is an osseous buckler, which exists also in *Megalops* and *Elops*, though of smaller size in those genera. The dorsal fin, beginning between the pectorals and ventrals, extends nearly to the caudal; the anal is short. Each nostril has a small tubular appendage. The stomach is ample and fleshy; the intestine without cæca. The swimming bladder is cellular, like the lung of a reptile.

Only one species, *Amia calva*, is known. It resides in the rivers of Carolina, where it feeds on crabs. It is seldom eaten.

Genus Sudis, Cuv. The characters of this group are nearly the same as those of *Erythrinus*, excepting that their body is proportionally longer, and the dorsal and anal fins are placed opposite to each other, and, nearly of an equal size, occupy the posterior third of the length of the body. The species live in fresh water.

Three kinds are now known. One, *Sudis Adansonii*, Cuv., was found in Senegal by Adanson, and in the Nile by Rüppel. Another, of a much larger size, with great bony scales and an oblong muzzle, is a native of Brazil,—the *Sudis gigas*, Cuv. A third, *Sudis Niloticus*, discovered by Ehrenberg in the Nile, has a singular spirally convoluted funnel adhering to the third gill, which may be analogous to what has been observed in *Anabas* and neighbouring genera.

Genus Osteoglossum, Vandelli. Distinguished from *Sudis* principally by two barbels, which depend from the symphysis of the lower jaw; the anal and caudal fins are united. The tongue is rendered very rough by a covering of short straight teeth, so that it may be used as a rasp to reduce fruits to a pulp.

Osteoglossum Vandellii, Cuv., is a native of Brazil.

Genus Lepisosteus, Lacép. Muzzle formed by the union of the maxillaries, inter-maxillaries, and palatines, with the vomer and ethmoid, which the lower jaw equals in length. The jaws have along their edge a row of long and pointed teeth, and their inner surface is rendered bristly by a covering of sharp, rasp-like teeth. The gill-covers are united below by a common membrane, having three rays on each side. These fishes are covered with scales of a stony hardness. The dorsal and anal fins, which are opposite to one another, are both situate very far back. The two outer rays of the tail, and the first ray of all the other fins, are furnished with scales so as to make them appear dentated. The pylorus has many short cæca. The swimming bladder is cellular, as in *Amia*.

There appear to be several species or varieties of this fish. They inhabit the rivers and lakes of the warm parts of America. They grow to a considerable size, and are considered to be good eating. Dr Fleming observes, that the claims of *Lepisosteus osseus* to rank as a British species are very doubtful. Berkenhout indeed has inserted it in his *Synopsis* (p. 81), with the habitat of *Sussex coast;* and Mr Stewart, in his *Elements of Nat. Hist.* (vol. i. p. 374), intimates its occurrence in the Firth of Forth; but we are not aware of its having been seen among us in recent times. We here figure the *Lepisosteus spatula* of Lacépède (*Esox Cepedianus*, Shaw), a native of the seas and rivers of America. Plate CCCV. fig. 4.

Genus Polypterus, Geoff. Distinguished at once from other genera by a number of separate fins placed along the back, each supported by a strong spine, to the posterior edge of which are attached some soft rays. The caudal fin surrounds the end of the tail, and the anal is very near it; the ventrals are very far back. The body is covered with bony scales like those of the preceding genus, and the whole cheek is covered by an osseous plate, shagreened in a similar manner to those on the rest of the head. Around each jaw there is a row of conical teeth, and behind some close or rasp-like teeth. Their stomach is capacious, the intestine narrow, with a spiral valve and one cæcum. The swimming bladder is double, with large lobes, particularly that on the left side, communicating by a wide aperture with the œsophagus.

Polypt. bichir (*P. Niloticus*, Shaw) may be named as a species of the genus. It has sixteen dorsal fins, and was discovered by M. Geoffroy in the Nile. (See Plate CCCV. fig. 3.) *Polypt. Senegalus*, Cuv. is another species from Senegal. It has only twelve dorsal fins. The flesh of these fish is good eating.

ORDER III.—MALACOPTERYGII SUB-BRACHIATI.

This order is characterised by the attachment of the ventral fins beneath the pectorals,—which latter may be regarded as analogous to the arms, and hence the name *Sub-brachian*. The pelvis is suspended immediately from the bones of the shoulder.

This order contains as many families as Linnæan genera.

FAMILY I.—GADIDÆ.

Comprehends the members of the great Linnæan genus Gadus, containing the well-known cod and haddock.

The Gadi in general are recognised by the ventral fins being pointed and attached to the throat. The body is moderately elongated, slightly compressed, and covered with soft and not very large scales. The head is well proportioned, and without scales; all the fins are soft. The jaws, and the front of the vomer, are armed with several rows of pointed, irregular, middle-sized, or small teeth, forming a sort of currycomb or rasp. Their gill-covers are large, with seven rays. Most of the species have two or three fins on the back, one or two behind the anus, and a distinct caudal. Their stomach forms a large muscular sac; the cæca are very numerous. The swimming bladder is large, and has strong parietes, frequently dentated on the sides.

These fishes generally live in cold or temperate climates, and constitute a very important article of fishery. The greater number are considered wholesome, and form a light and agreeable food,—the flesh separating easily by boiling, into white flaky layers. The great sand bank of Newfoundland is the most famous station of the cod fisheries, and is resorted to by English fishermen, who chiefly use the hook and line. The fish abound in this place probably on account of the great quantity of the smaller animals which serve as food, viz. mussels, clams, &c.

The family of Gadidæ has been divided by Cuvier into Morrhua, or cods properly so called, Merlangus or whitings, Merluccius or hakes, Lota or lings, Motella, Brosmius, Brotula, Phycis, and Raniceps.

Genus Morrhua, Cuv. Has three dorsal fins and two anal; a tuft at the point of the lower jaw. The species are extremely prolific.

M. vulgaris (*Gadus morrhua*, L.). The common cod (*la Morue*, Fr.; *Kabliau*, Germ.) measures from two to three feet in length. The back is spotted with yellowish brown. It inhabits the whole Northern Ocean, and occurs in vast profusion.

This fish dwells in salt water only. It is not found nearer the equator than the 40th degree of latitude. The weight of the common cod varies from twelve to eighty or even 100 pounds. It is extremely voracious, and its digestive powers are seemingly very great. It feeds upon smaller fishes, such as herrings, on Mollusca, worms, and Crustacea, and even on the young of its own species. It has a strong muscular stomach, and is said to possess the power of rejecting by the mouth substances, such as wood, &c. which it finds indigestible.

In spring they come nearer the shore in order to deposit their spawn. This happens in January in England, in February in Norway, Denmark, and Scotland, and in March in Newfoundland. One female is said to contain from *four* to *nine millions* of eggs!

The most extensive cod fisheries on our coasts are off the Western and Shetland Isles, but they are still greater in more northern countries. The cod has been fished on the coast of Sweden since the year 1368, by the inhabitants of Amsterdam. The English resorted to Iceland before the year 1415; and it is stated that in the year 1792, 200 French vessels of a burden of 191,153 tons were employed in the cod fishery. Every year more than 6000 European vessels are employed in this fishery.[1]

The flesh of the cod has a good flavour, and may be easily preserved. The tongue, salted and dried, has been considered a great delicacy. The gills are preserved and used as bait. The liver is eaten, and is sometimes used for the production of oil. The swimming bladder affords a very good isinglass.

This important species constitutes a principal article of food to the inhabitants in some parts of Iceland, Norway, and other northern countries. In a dried state it is also much used in some papal kingdoms of the south.

In the neighbourhood of the Isle of Man, and elsewhere, there is a variety of the cod named the red or rock cod, the skin of which is of a brightish vermillion colour. Its flesh is much esteemed.

[1] We cannot in this place enter upon the important subject of *Fisheries;* but the reader may consult with advantage Pennant's *British Zoology*, vol. iii. and Duhamel's *Traité Général des Pesches.*

M. æglefinus (*Gadus æglefinus*, Linn.). The haddock (*l'Egrefin*, Fr.; *Schollfisch*, Germ.) is as well known, and almost as important, as the cod in this country; it is of a smaller size, usually eighteen inches long. The back is brown, the belly silvery, and the lateral line black. There is a blackish spot behind the pectoral fin, which tradition assigns to the impression of St Peter's finger and thumb when he took the tribute-money out of the mouth of a fish, supposed the haddock. The upper jaw is longest.

The haddock is found, like the cod, in the Northern Ocean, but has not been seen in the Baltic. It annually approaches the shores, in February and March generally, in order to deposit its spawn. The regularity with which it re-appears in some districts on a stated day is quite remarkable. On the coast of Yorkshire, since the year 1766, they have annually made their appearance on the 10th of December. At this place they are supposed to form an immense shoal three miles broad, and extending eighty miles in length,—from Flamborough Head to the mouth of the Tyne. It is in autumn that they visit the shores of Holland and East Friesland, and the neighbourhood of Heligoland.

The haddock frequents our coasts during the greater part of the year, although the largest are taken in winter. The flesh is generally best in the months of May and June.

It is stated, that in the north, when the sea is frozen near the shore, these fish collect in troops beneath any openings in the ice, and the Greenlanders are thus enabled to catch them in considerable numbers. The seals and foxes adopt the same method of securing them for food. The food of the haddock is very similar to that of the cod, which species it resembles in its voracious habits.

M. callarias (*Gadus callarias*, Linn.). The dorse (*Faux Merlan*, Fr.) is smaller than the haddock, being only eleven or twelve inches long. It is spotted like the cod, and has the upper jaw longer than the under. The lateral line is placed near the back. It resembles the whiting in taste, and is considered by many as the best eating fish of all the Gadus tribe. It is much sought after on the shores of the Baltic.

This fish frequents the mouths of large rivers, which it sometimes ascends along with the salt water. It is generally taken in June. The Icelanders salt and dry it, and the Greenlanders are said frequently to eat it in a state of semi-putrefaction.

To these fishes, which are among the best-determined species of the old genus Gadus, may be added *Gadus barbatus* or whiting pout, a fish about eighteen inches or two feet long, which is eaten by the Greenlanders, but not much esteemed. *Gadus minutus*, the capelan or poor, *Gadus punctatus*, the speckled cod, and *Gadus luscus*, the bib, may be named as other species which occur along the British shores.

Genus Merlangus, Cuv. The whitings have the same number of fins as the cods, but they want the barbels.

M. vulgaris (*Gadus merlangus*, Linn.). The whiting, *Merlan*, Fr.; *Witling*, Germ. The body a foot or more in length; upper jaw long; pale reddish-gray back, and silvery belly; lateral line yellow, nearly straight.

This fish is very common on our coasts, and is valued on account of its abundance, and the wholesomeness and fine flavour of its flesh. It is often salted and dried in this country, as well as in Holland. The shoals of whitings sometimes occupy a space three miles long, and one and a half broad. It is generally fished in summer in this country, and is taken both with the line and net. The food of the whiting is similar to that of the haddock. It is more frequently found near the shore than that species.

M. carbonarius (*Gadus carbonarius*, L.). The coal-fish (*Merlan noir ou Colin*, Fr.; *Kohlfisch*, Germ.) is twice the size of the whiting, and of a deep brown colour; the upper jaw shortest; the lateral line straight and white. The flesh of the young is rather delicate; that of the adult is somewhat leathery, but it is used when salted and dried, like the cod. This is the *podley*, *silloch*, *cuddy*, &c. of our coasts. The young swarm along the British shores, and form a frequent sustenance of the lower orders of the Western Highlands. On one occasion we killed thirty-three dozen with the rod in a few hours, using a line with six small flies. By giving the line one or two additional turns through the water, we frequently pulled six ashore at once. It even constitutes an important article of exportation from our northern coasts. In Norway the poor feed upon it; and oil is made from its liver. The adult fish is taken principally in summer; it deposits its spawn in this country in February and March. The coal-fish is found in the North Atlantic and Pacific Oceans; and sometimes, though very rarely, in the Mediterranean Sea,—for example, near Nice.

M. pollachius (*Gadus pollachius*, L.). The pollock or pollack, *Merlan jaune*, Fr. About eighteen inches long; resembles *M. carbonarius* in its general form and structure of the jaws; brown above and silvery beneath; sides spotted; lateral line curved, black. The flesh of the pollock is considered better than that of the coal-fish, and inferior only to that of the dorse and whiting; it inhabits the Atlantic, and is gregarious. It is commonest on the coasts of Norway and the north of England, and sometimes occurs in the Mediterranean in winter. It is easily caught with a white fly.

Gadus virens, Ascan., the sey, may also be included in the genus Merlangus.

Genus Merluccius, Cuv. The hakes have only two dorsal fins and one anal, and resemble the whitings in the absence of the barbels.

M. vulgaris (*Gadus merluccius*, L.). The hake (*le Merlus*, Fr.) is generally from one to two feet long, but sometimes much larger. The back of a brownish-gray colour; the anterior dorsal fin pointed; the lower jaw longest.

Great numbers are taken in the ocean, and in the Mediterranean. On the coasts of the Mediterranean it is called merlan or whiting; and, when dried, it receives in the north the name of stock-fish, in the same way as the cod. It is said to be very abundant in the Bay of Galway on the west of Ireland, and at Penzance in Cornwall. The flesh is white and flaky, and its liver is considered a delicacy.

Gadus magellanicus, Forst., and *Gadus maraldi*, Risso, may be included in this group.

Genus Lota, Cuv. The *lings* have the same fins as the hakes, but are also provided with barbels to a greater or less amount.

Lota molva (*Gadus molva*, L.) or common ling (*la Lingue*, or *Morue longue*, Fr.), is the best-known species. It measures from three to four feet in length, and sometimes even attains the size of seven feet; it is named ling from its lengthened shape. Olive above, silvery beneath. The fins have a white margin; the two dorsal fins are of equal height. The lower jaw rather the shortest, and furnished with a single barbel.

This fish spawns in June; it inhabits the same seas as the cod, and is fished in the same manner during the spring months. It is preserved dry, and exported in considerable quantity.

Lota fluviatilis (*Gadus lota*, L.), river ling or burbot (*la Lotte commune*, Fr.), is from one to two feet long. Its colour yellow, marbled with brown; a single barbel on the chin. The two dorsal fins are of equal height, the second extending to near the tail. The body is almost cylindrical, and the head slightly depressed, so as to give the fish a peculiar appearance, somewhat resembling that of an eel; hence its occasional name of Eel Pout. See Plate CCCV. fig. 5.

This is the only Gadus which inhabits fresh water; it ascends rivers to a considerable distance, and inhabits lakes. It is very abundant in North Asia and the Indies. It is also well known in North America. In England it is found only in a few rivers. The flesh and liver of the burbot are esteemed.[1]

To this sub-genus may be added *Gadus Bacchus*, Forst., *Gadus maculosus*, Lesueur, and *Lota elongata*, Risso.

Among the lings, Cuvier has distinguished another small group named

GENUS MOTELLA, Cuv., in which the anterior dorsal fin is so small as scarcely to be perceptible.

As species we may name *Gadus mustela*, L. described by Bloch as *G. tricirrhatus.* It is of a fawn-coloured brown, with blackish spots; two barbels on the upper jaw, and a third on the lower one. *Gadus cimbricus*, Schn. (*G. quinquecirrhatus*, Penn.) is also a *Motella.* The species are called *Gades* by English writers.

GENUS BROSMIUS, Cuv. The *torsks* or *tusks* have only one dorsal fin, which extends nearly the whole length from the head to the tail.

B. brosme, or Scotch torsk, seldom ventures farther south than the Orkneys or Caithness; it is very numerous near the Shetland Isles. It is called *Brosme* by the fishermen, from its resemblance to the blenny genus. The name of torsk is applied in Norway and Sweden to the *Gadus callarias* (a true *Morrhua*), which has three dorsal fins. This circumstance has given rise to some confusion. Donovan described the Scotch torsk from a specimen sent him alive from Shetland. It is salted and dried in the north.

GENUS BROTULA, Cuv. Dorsal and anal fins united with the caudal, so as to form a single fin, terminating in a point.

One species only (*Enchelyopus barbatus* of Bloch and Schneider) is known. It has six barbels, and comes from the Antilles.

GENUS PHYCIS, Art. and Schn. Differs from the other Gadi in having ventral fins with only one ray,—frequently forked. The head is thick, the chin with one barbel. Two dorsal fins, the second of which is long. Some species are found in European seas.

Such is *Phycis Mediterraneus*, Laroche, sometimes called the sea tench (*Blennius phycis*, Linn.). Anterior dorsal round, and not higher than the other; the ventrals of the same length as the head. This is a common species in the Mediterranean.

Phycis blennoides, Schn., *S. furcatus*, or forked hake of Pennant, occurs also in the ocean. The first dorsal fin is more elevated, and its first ray considerably elongated; the ventral fins are twice the length of the head. It is a British species, though a rare one.

GENUS RANICEPS, Cuv. The head more depressed than in Phycis and the other Gadi; the anterior dorsal fin so small that it is lost in the thickness of the skin. Inhabits the ocean.

The trifurcated hake of Pennant belongs to this genus.

GENUS MACROURUS, Bl. *Lepidoleprus*, Risso. The suborbitals unite in front with each other and with the bones of the nose, so as to form a depressed snout, which projects above the mouth, and beneath which the latter preserves its mobility. The head and body are covered with hard and spiny scales. The ventral fins are small and somewhat jugular; the pectorals of moderate size; the first dorsal short and high; the second dorsal and anal both very long, and uniting with the caudal; very fine short teeth in the jaws.

The species inhabit deep water, and when taken from it utter sounds resembling those of the genus *Gristes.* Only two species have been as yet described, the *Lep. cælorhynchus* and *trachyrynchus* of Risso. They occur both in the Mediterranean and along the oceanic coasts of France.

FAMILY II.—PLEURONECTIDÆ.

This family of the sub-brachian malacopterygian order comprehends the great Linnean genus PLEURONECTES, which includes all those osseous species usually known under the name of *flat fish.*

They are at once distinguished by a character unique among vertebrated animals, viz. the want of symmetry in the construction of the head; both eyes being placed on the same side, or on that which remains uppermost when the animal swims, and which is always of a darker colour; while the side in which the eyes are wanting faces the ground, and is always whitish, or very pale. Some of the other organs participate in this irregularity of the orbits; thus the two sides of the mouth are unequal, and the two pectoral fins are generally of different sizes. Their body is much compressed, and raised vertically. The dorsal fin runs along the whole of the back, the anal occupies what may be regarded as the under part of the body, and the ventrals have almost the appearance of continuing that fin forwards, so much do they often appear as if united together. There are six rays in the branchiostegous membrane. The abdominal cavity is small (the anus being far forwards); but it is prolonged into a sinus in the thickness of the two sides of the tail, in which some portion of the viscera is lodged. There is no swimming bladder, and these fishes seldom quit the bottom.

The PLEURONECTIDÆ furnish an agreeable and wholesome food, and occur along the coasts of almost all countries. The disposition of the bones of the head is curious, on account of the inversion which brings the two orbits to the same side; still we recognise in it all the pieces common to the other genera, but of unequal size. Individuals termed *reversed* are sometimes found, having the eyes placed on a different side from that on which they are situated in the rest of their species. Others, having the two sides of the body of the same colour, are called *double.* The brown or upper side is more frequently thus repeated than the white one; but the *rose-coloured flounder* of Shaw presents an instance of the duplication of the paler side.[2]

The genus *Pleuronectes* was formerly subdivided according as the eyes were placed on the right or left side of the middle line; but, on account of the irregularity of individuals in this respect, Cuvier has rejected the character, and has distinguished various groups, as follows:

GENUS PLATESSA, Cuv. Has on each jaw a range of obtuse cutting teeth, and generally some teeth in the form of pavement (*en pavés*) on the pharyngeal bones. The dorsal fin advances forwards as far as the upper eye, and leaves, as well as the anal, a naked interval between it and the caudal. The form of the body is rhomboidal; the majority have the eyes on the right side. They have two or three small cæca. Several inhabit the British seas.

---

[1] "*On estime fort sa chair*, et surtout son foie, qui est singulièrement volumineux," observes Baron Cuvier, *Règne Animal*, t. ii. p. 334. A different opinion, however, has been formed of it in the western world. "The burbot," says Dr Richardson, "is so little esteemed as food, as to be eaten only in cases of necessity. Very good bread, however, may be made of the roe, and the livers are always prized. *Dogs will scarcely ever eat this fish.*" (*Appendix* to Captain Franklin's first *Journey to the Polar Sea*, p. 724.) Dr R. adds, that this species preys upon every kind of fish that it can swallow, and that in spring its stomach is generally so crammed with cray-fish as to distort the shape of the body.

[2] *Gen. Zool.* vol. iv. part 2, pl. xliii.

P. vulgaris (*Pleuronectes platessa*, L.). The plaice (*Carelet*, Fr.; *Scholle*, Germ.) is recognised by six or seven tubercles forming a line on the right side of the head between the eyes, and by spots of a bright yellow colour, which relieve the brown of the body on that same side. This fish is three times as long as it is high. Plate CCCV. fig. 6.

The plaice grows sometimes to the size of fifteen or sixteen pounds weight, but those weighing seven or eight pounds are considered large; its flesh is more tender than that of any other species of the genus. It inhabits the Mediterranean, Baltic, and North Seas, and spawns in spring.

A large plaice, *Pl. borealis*, Fabr., having the spine behind the anus concealed under the skin, is described as belonging to the northern regions.[1]

Pl. latus, Cuv. The broad plaice (*la Plie large*, Fr.) is a much rarer species. It has the same tubercles as the common plaice, and differs from it chiefly in being only once and a half as long as it is high.

Pl. flesus, L. The flounder (*le Flet ou Picaud*, Fr.; *der Flünder*, Germ.) has nearly the same form as the plaice, with paler spots; it has only small granular eminences at the salient line of the head, and at the base of each ray of the dorsal and anal fins there is a small rough projection; the lateral line has also bristly scales. Many of this species occur reversed.

The flounder is taken in spring near the shore, and at the mouths of rivers, into which it sometimes ascends a considerable way; it lives well in fresh water, and is kept in ponds in Friesland. It inhabits the Baltic and North Atlantic Seas. Its flesh is much inferior to that of the plaice; the best are said to be taken near Memel.

Pl. pola, Cuv., is a fish described by Duhamel under the name of *La Vraie Limandelle.* It is of an oblong form, approaching to that of the sole, although broader. It is distinguished from other *Platessæ* with sharp teeth, by a smaller head and mouth. The body is smooth and the lateral line straight. In France it is considered as equal to the sole.

Pl. limanda, L. The dab or bret (*la Limande*, Fr.; *die Glahrke*, Germ.) is of a rhomboidal form, like the flounder; has large eyes, and a salient line between them. Its lateral line is strongly curved above the pectoral fin. Its scales are rougher than in the preceding species, and to this character it owes its name (from *lima*, file). Its teeth, though in a single row, as in other *Platessæ*, are narrower, and almost linear. The side on which the eyes are placed is of a clear brown, with some indistinct brown and whitish spots. This is a small fish, its length being less than a foot; but it is much esteemed. It is less common than either the plaice or flounder. It spawns in May, and is in season for the table during spring.

Genus Hippoglossus, Cuv. Has a form of body, and fins, similar to the plaices; the jaws and pharynx are armed with sharper and stronger teeth. Their form is generally more oblong.

H. vulgaris (*Pl. hippoglossus*, L.). The great holibut, or halibut (*le grand Flétan ou Helbut*, Fr.; *die Heiligbutte*, Germ.), is one of the largest of this genus inhabiting the northern seas. It sometimes attains a very great size, for example, to the length of six or seven feet, and weighing three or four hundred pounds. The skin is smooth; it has the eyes to the right side; the lateral line arched above the pectoral fin; there is a long spine before the anal fin.

This is the most voracious of all the Pleuronectidæ, preying on smaller fishes, Crustacea, Mollusca, &c. It inhabits the Mediterranean, as well as the northern seas. The flesh of the young is esteemed, and is not seldom sold to the uninitiated for turbot, to which, however, it is much inferior in every way. Indeed, when old, it is extremely coarse.[2]

In the Mediterranean there are several smaller species, of which some have the eyes to the left side. Such is *Pl. macrolepidotus*, Bl.—*Citharus*, Rond.; distinguished by the large size of its scales, its oblong form, and straight lateral line. (Plate CCCV. fig. 7.) *Pl. cynoglossus* is described by Shaw as a smaller holibut, found in considerable quantity in Greenland, and superior to the common kind as an article of food.

Genus Rhombus, Cuv. The turbots, like the holibuts, have teeth closely set, or *en carde*, both on the jaws and pharynx; but their dorsal fin advances as far as the edge of the upper jaw, and extends, in common with the anal, to near the caudal fin. The greater number have the eyes to the left.

In some the eyes are approximate, and in the interval between them there is a slight projecting crest. The two largest of our coasts are of this kind; they are the most esteemed as food of all the Pleuronectidæ.

Rh. maximus (*Pl. maximus*, L.). The turbot, *le Turbot*, Fr.; *Steinbutte*, Germ. This fish, so highly prized on account of its delicate flavour, and the wholesomeness of its flesh, is distinguished by the rhomboidal shape of its body, which is nearly as high as it is long. It is bristled on the brown side with small tubercles; has the lateral line curved; and the eyes on the left side.

This species is usually much smaller than the holibut; it is frequently two feet long, with a weight of twenty pounds; but it is stated sometimes to attain the length of five or six feet. Extensive turbot fisheries are established on different parts of our coast. The turbot is taken with the hook; it is very voracious, and may be lured by various baits, such as portions of herring or haddock, mussels, limpets, and other shell-fish; but all these must be very fresh. Indeed the species very sensibly prefers live bait without hooks, more especially the small river-lamprey. Mr Pennant has particularly described the extensive turbot fishery at Scarborough. There are three men in each of the fishing-boats, each man having three lines, and each line 280 hooks. All the nine lines are fastened together, and then extend to about three miles in length; they are laid across the current, and are allowed to remain for six hours before they are hauled. This fish is called the water or sea-pheasant, by the French common people, on account of its fine flavour.

Rh. rhombus. The pearl or brill, *la Barbue*, Fr. The body more oval than that of the turbot; without tubercles; and distinguished besides by the first rays of its dorsal fin being half free, with their extremities divided into several strips. This fish is of a smaller size than the turbot; it has a delicate flavour, and is in great request.

Rh. punctatus; Pl. lævis, Shaw. The kitt (*le Targeur*, Fr.) is much rarer than the preceding on our coasts. Its shape is oval like the brill; it has no strips on the rays of its fins; its scales are rough; its teeth very fine; its cheek furnished with very close and even teeth; and it has black points and spots on a brown ground. It is said to be more frequent in Shetland than along the other British coasts.

Rh. cardina. The whiff (*la Cardine*, or *Calimande*, Fr.) is quite of an oblong form; its first rays are free, but simple;

[1] *Isis*, xxi. p. 868.

[2] Nevertheless it is generally called *turbot* in the Edinburgh market, where the true turbot passes under the classical cognomen of *roun-fleuk*.

its teeth very close and even. It has spots partly white and partly blackish, scattered on a brown ground. This species is taken, though seldom, in the Channel.

In the Mediterranean there is a small species, only a few inches long,—*Pl. nudus*, Risso; *Arnoglossum*, Rond.; and another still smaller, which is quite transparent,—*Pl. candidissimus*, Risso; *Pl. diaphanus*, Schn.

In other turbots the eyes are distant, the upper one far back; their interval is concave; they have a small projecting hook on the base of the maxillary bone at the side on which the eyes are placed, and sometimes another on the inferior eye. There are several of this nature in the Mediterranean, such as the *Pl. podas* of Laroche.[1] We have figured *Pl. argus* on Plate CCCV. fig. 8.

Genus Solea, Cuv. The soles have, as a distinguishing character, the mouth twisted to the side opposite the eyes; that side only being furnished with teeth, which are fine, like the pile of velvet, or, according to Cuvier's frequent expression, *en velours;* the side on which the eyes are placed is toothless. Their form is oblong; the snout round, and almost always projecting more than the mouth. The dorsal fin commences at the mouth, and extends, as well as the anal, to the caudal fin. The lateral line is straight; the side of the head opposite to the eyes is furnished with a kind of villosity. The intestine is long; it forms several folds, but has no cæca.

S. vulgaris (*Pl. solea*, L.). The sole (*le Sole*, Fr.) is a species common on the European coasts, and universally esteemed wherever known. Brown on the side which bears the eyes; the pectoral fin spotted with black. It is one of our most valued fishes for the table, the flesh being firm, white, and of delicious flavour. The sole generally measures from one to two feet in length, and its weight varies from one to seven pounds. It is a gregarious fish, and is generally taken with the trawl-net. It inhabits the Baltic, North, Atlantic, and Mediterranean Seas. There is a large sole fishery at Brixham in Torbay, and a very extensive one on the coast of Sardinia. The best soles are said to be found at the Cape of Good Hope; yet our honoured friend Justice Menzies does not esteem them so highly as he did those of his native Scotland.

There are many distinct species of this genus, besides numerous varieties that have been too vaguely described to admit of their being easily distinguished from each other. We shall here merely name the *Pallasian*, *Zebra* (Plate CCCV. fig. 9), *Carolina*, *Ocellated*, *Rondeletian*, *Platessoid*, *Silver*, *Smooth*, *Bearded*, *Marbled*, *Pavonian*, and *Variegated* Soles.

Genus Monochirus, Cuv. Contains such soles as have only a very small pectoral fin on the side of the eyes, the one on the opposite side being either very minute, or wholly wanting. There is one Mediterranean species, the *Pl. microchirus* of Laroche.[2]

Genus Achirus, Lacép. Contains the species which are wholly destitute of pectoral fins; and which may again be divided according as their vertical fins are distinct, as in *Achiri* properly so called, or united to the caudal fin, as in the sub-genus *Plagusia*.

FAMILY III.—DISCOBOLI.

Forms the concluding division of the sub-brachian malacopterygian fishes. They receive their name from the disk formed by their ventral fins. This family comprehends two genera, neither of which is numerous.

Genus Lepadogaster, Gouan. The ample pectoral fins descend to the inferior surface of the body, and become united together beneath the throat by a transverse membrane, directed forwards, which is formed by the union of the two ventral fins. The body is smooth and without scales; the head broad and depressed; the muzzle projecting and extensile; the branchial openings small; the gill-covering furnished with four or five rays. There is only one soft dorsal fin, opposite to an anal of a similar kind. The intestine is short, straight, and without cæca. There is no swimming bladder, but nevertheless the species swim rapidly along the shores. The genus is divisible as follows:

1*st*, Lepadogaster properly so called. The membrane already mentioned, which takes the place of the ventral fins, extends circularly under the pelvis, and forms a concave disk; on the other hand, the bones of the shoulder form a slight projection behind, which completes a second disk with the membrane uniting the pectorals.

Several species inhabit the Mediterranean and neighbouring seas. In some the dorsal and anal fins are distinct from the caudal, with which their membrane is however sometimes continuous, though it at the same time becomes narrower. Of this kind are the *Lep. Gouani*, *balbis*, and *Decandolii*. In others, these three fins are united, as in *L. Wildenovii*. The *Cyclopterus cornubicus* of Shaw (*Jura sucker* of Pennant) belongs to the genus Lepadogaster.

2*d*, Gobiesox, Lacép. Interval between the pectoral and ventral fins not divided into a double disk, but forming only a large single disk, cleft on both sides, and prolonged by the membranes. The dorsal and anal fins are short, and distinct from the caudal. The branchial apertures are larger than in the preceding. A British species, known under the name of bimaculated sucker (*Cyc. bimaculatus*, Pennant), belongs to this genus. It is a very small fish, not measuring more than an inch and a half. Montagu found it adhering to stones and old shells, and obtained it in abundance, by dredging, near Forcross.[3]

Genus Cyclopterus, Linn. The circle-finned fishes, commonly called *suckers* or *lump-fish*, have a well-marked character in their ventral fins, the rays of which, suspended all round the pelvis, and united by a single membrane, form an oval and concave disk, which the fish employs as a sucker to fix itself to the rocks. Besides this, their mouth is wide, and furnished on both jaws and pharyngeal bones with small pointed teeth. Their opercles are small; their branchial openings closed towards the bottom, and furnished with six rays. Their pectoral fins are very large, and unite almost under the throat, embracing as it were the disk of the ventrals. Their skeleton does not harden much; and their skin, viscous and without scales, has small hard grains scattered here and there upon its surface. They have a stomach of considerable size, many cæca, a long intestine, and a swimming bladder of ordinary dimensions.

The Cyclopteri are divided by Cuvier into two sub-genera, as follows:

1*st*, Lumpus. Has a first dorsal fin, more or less perceptible, though very low, and with simple rays,—and a second one with branched rays opposite to the anal. The body is thick.

Cycl. lumpus, L. (Plate CCCV. fig. 11.) The lump-fish or sucker (*le Lump*, *Gras Mollet*, Fr.; *See Hase*, Germ.) has its first dorsal fin so much enveloped in a thick tubercular skin, that externally it might be taken for a mere hump on the back. It is furnished with three rows of conical tubercles on each side.

This fish is about eighteen inches long. It lives, especially in the north, on Medusæ and other gelatinous animals. Its flesh is soft, insipid, somewhat oily, and is sel-

Malacopterygii Sub-brachiati. Discoboli.

dom used for food by those who can provide better. It is, however, held in some estimation by the Greenlanders, themselves an oily people, whose lines do not always fall in pleasant places. They also eat its roe (which is a very large one), after having reduced it by boiling to a pulp. In Ireland it is sometimes salted. This fish is very unwieldy, and, possessing few means of defence, it generally remains at the bottom of the sea, adhering to the rocks. It thus becomes an easy prey both to seals and sharks. Large placid oily spots upon the surface of the sea are often seen above the places where the lump-fish have been seized and slain. We also occasionally find their skins floating empty along the shore, the flesh and blood having been previously extracted by their insatiate foes. The male is said to preserve with great care the eggs which he has fecundated, and he has moreover been famed in fable for his affectionate behaviour to the female. There does not, however, appear to be any real foundation for this trait in his character,—a very unfrequent one in that of any member of the fishy tribes.

Cyclopt. spinosus inhabits the northern seas. *Cycl. minutus* is found in the Atlantic, and *C. nudus* in the Indian Ocean.

2*d*, Liparis, Artedi. Has only one dorsal fin, which, as well as the anal, is rather long. The body is smooth, elongated, and compressed behind.

Lip. vulgaris (*Cyc. liparis*, L.), the unctuous sucker of Pennant, is a European species of variable size, not uncommon about the mouths of rivers, especially those of the northern seas. It is a well-known British species, remarkable not merely for dying, but for actually *dissolving*, soon after it is taken out of the water. *Liparis Montagui* measures only about two inches in length.[1] It was discovered by the naturalist whose name it bears, among the rocks at Milton, on the south coast of Devon, during some extraordinary low tides. *Lip. gelatinosus* is another northern species, the flesh of which is not eatable, as described by Pallas in his *Spicilegia Zoologica.* Its flesh is so bad that not even dogs will eat it.

Genus Echeneis, Linn. This genus, so different from its neighbours, might, like the old Linnæan genus Pleuronectes, almost form a separate family of the sub-brachian malacopterygian fishes. The species called *Remoras* are remarkable for the flattened disk they bear upon their heads, and by means of which they can adhere to other bodies with considerable firmness. These disks are composed of a certain number of transverse cartilaginous plates, directed obliquely backwards; dentated or spinous at their posterior edge, and moveable in such a manner that the fish can create a vacancy between them; and thus, aided also by the toothed margin, it fixes itself securely either to rocks or floating bodies.

This genus has the body elongated, and clothed with small scales; a single soft dorsal fin opposite to the anal; the head quite flat above; the mouth cleft horizontally, and rounded; the lower jaw placed more forwards, and furnished, as well as the inter-maxillary bones, with small pectiniform teeth. There is a row of regularly-set small teeth, like cilia, along the edge of the maxillaries, which form the external margin of the upper jaw; the vomer is furnished with cardiform teeth, as well as the tongue. They have eight branchiostegous rays. Their stomach is a wide cul-de-sac; the cæca six or eight in number; the intestine wide, but short. They have no swimming bladder.

The species are few in number. Of these, *Echeneis remora*, Linn., the famous *Remora*, or sucking fish, of the Mediterranean, is the best known. It has usually eighteen plates in its cranial disk.

The extraordinary power possessed by this fish, of adhering tenaciously to any flattish surface, was known to ancient writers, as well as to the curious inquirers of modern times. Pliny luxuriates upon it with his usual discursive verbosity. The reader may possibly be amused by Philemon Holland's translation of the passages in question. "Having so far proceeded in the discourse of nature's historie, that I am now arrived at the very heigth of her forces, and come into a world of examples, I cannot chuse but in the first place consider the power of her operations, and the infinitnesse of her secrets, which offer themselves before our eyes in the sea: for in no part else of this universal frame is it possible to observe the like majestie of nature: insomuch, as we need not seeke any farther, nay, we ought not to make more search into her divinitie, considering there cannot be found any thing equall or like unto this one element, wherein she hath surmounted and gone beyond her own selfe in a wonderfull number of respects. For, first and foremost, is there any thing more violent than the sea; and namely when it is troubled with blustring winds, whirlepuffs, storms, and tempests? or wherein hath the wit of man been more employed (seeke out all parts of the known world) than in seconding the waves and billows of the sea, by saile and ore? Finally, is there ought more admirable than the inerrable force of the reciprocall tides of the sea, ebbing and flowing as it doth, whereby it keepeth a current also, as it were the stream of some great river?

"The current of the sea is great, the tide much, the winds vehement and forcible; and more than that, ores and sailes withall to help forward the rest, are mightie and powerfull: and yet there is one little sillie fish, named echeneis, that checketh, scorneth, and arresteth them all. Let the winds blow as much as they will, rage the storms and tempests what they can, yet this little fish commaundeth their furie, restraineth their puissance, and, maugre all their force, as great as it is, compelleth ships to stand still: a thing which no cables, be they never so big and able as they will, can perform. She bridleth the violence and tameth the greatest rage of this universall world, and that without any paine that she putteth herselfe unto, without any holding or putting backe, or any other meanes save only by cleaving and sticking fast to a vessell: in such a sort as this one small and poore fish is sufficient to resist and withstand so great a power both of sea and navie, yea and to stop the passage of a ship, doe they all what they can possible to the contrarie. What should our fleets and armadoes at sea make such turrets in their decks and forecastles? what should they fortifie their ships in warlike manner, to fight from them upon the sea, as it were from mure and rampier on firme land? See the vanitie of man! alas, how foolish are we to make all this adoe? When one little fish, not above half a foot long, is able to arrest and stay per force, yea, and hold as prisoners, our goodly tall and proud ships, so well armed in the beakehead with yron pikes and brazen tines; so offensive and dangerous to bouge and pierce any enemie ship which they doe encountre. Certes, reported it is, that in the naval battaile before Actium, wherein *Antonius*, and *Cleopatra* the queene, were defeited by *Augustus*, one of these fishes staied the admirall ship wherein *M. Antonius* was, at what time as he made all the hast and meanes he could devise with help of ores to encourage his people from ship to ship, and could not prevaile, untill he was forced to abandon the said admirall, and go into another galley. Meanwhile the armada of *Augustus Cæsar*, seeing this disorder, charged with greater violence, and soone invested the fleete of *Antonie.* Of late daies also, and within our remembrance, the like

[1] Donovan's *British Fishes*, t. lxviii.

Malacopterygii Sub-brachiati. Discoboli.

happened to the roiall ship of the emperor *Caius Caligula*, at what time as he rowed backe, and made saile from Astura to Antium; when and where this little fish detained his ship, and (as it fell out afterward) presaged an unfortunate event thereby: for this was the last time that ever this emperour made his returne to Rome: and no sooner was he arrived, but his own souldiours in a mutinie fell upon him and stabbed him to death. And yet it was not long ere the cause of this wonderfull staie of his ship was knowne: for so soon as ever the vessel (and a galliace it was, furnished with five bankes of ores to a side) was perceived alone in the fleete to stand still, presentlie a number of tall fellows leapt out of their ships into the sea, to search what the reason might be that it stirred not; and found one of these fishes sticking fast to the very helme: which being reported unto *Caius Caligula*, he fumed and fared as an emperour, taking great indignation that so small a thing as it should hold him back perforce, and check the strength of all his mariners, notwithstanding there were no fewer than foure hundred lustie men in his galley that laboured at the ore all that ever they could to the contrarie. But this prince (as it is for certain knowne) was most astonied at this, namely, that the fish sticking only to the ship, should hold it fast; and the same being brought into the ship and there laid, not worke the like effect. They who at that time and afterward saw the fish, report that it resembled for all the world a snaile of the greatest making: but as touching the form and sundrie kinds thereof, many have written diversly, whose opinions I have set downe in my treatise of living creatures belonging to the waters, and namely in the particular discourse of this fish: neither doe I doubt but all the sorte of fishes are able to doe as much: for this we are to believe, that Pourcellans also be of the same vertue, since it was well knowne by a notorious example, that one of them did the like by a ship sent from *Periander* to the Cape of Gnidos: in regard whereof, the inhabitants of Gnidos doe honour and consecrat the said Porcellane within their temples of *Venus*. Some of our Latin writers do call the said fish that thus staieth a ship, by the name of Remora."

Another species, *Echeneis Naucrates*, Linn. (Plate CCCV. fig. 10), commonly called the Indian Remora, has usually twenty-two plates upon the head. In its habits it resembles the preceding; but it seems to be more frequent in the seas of India and America, than in those of Europe. The manuscripts of Commerson, as quoted by Count Lacépède, inform us that it is common along the coasts of Mosambique, where it is made use of in a singular way for the purpose of catching turtles. A ring is first fastened round its tail, and then a long cord is attached to the ring. When thus accoutred, the fish, placed in a vessel of seawater, is carried out in a boat; and as soon as the fishermen perceive a sleeping turtle, they row gently towards it, and throw the remora into the water, with a sufficient length of cord. It seldom fails speedily to attach itself to the unconscious turtle, which by the tenacity of its adherence is immediately drawn towards the boat and captured.

A third species of remora is described by Mr Archibald Menzies as an inhabitant of the Pacific Ocean.[1] He has named it *Ech. lineata*. It is distinguished by having only ten transverse plates to its sucker. Mr Menzies found it adhering to a turtle. A fourth species (and these are all with which we are acquainted) has been more recently discovered by Baron Cuvier. The rays of its pectoral fins are bony, compressed, and terminated by a slightly notched *pallete*. He names it *Echeneis osteochir*.[2]

ORDER IV.—MALACOPTERYGII APODES

Malacopterygii Apodes. Anguilliformes.

which may be considered as constituting a single natural family, the

ANGUILLIFORMES,

or fishes with an elongated shape; a thick skin, on which scales are in general but indistinctly visible; and without *cæca* to their intestines. Almost all are provided with a swimming bladder, which often assumes a remarkable form.

The ancient unrestricted Genus Muræna of Linnæus is distinguished by the snake-like form of the body; the small opercles covering concentric branchiostegous rays, buried in the skin, and only opening posteriorly by a sort of tubular orifice. This structure, by giving a more perfect command over the closure of the gills, enables them to remain longer out of water without injury than the generality of fishes. They have scarcely-perceptible scales, which are concealed in a tough skin, covered with a slippery mucus. They all are destitute of ventral fins and cæca, and have the anus placed very far behind. Numerous subdivisions of the old genus *Muræna* have taken place in modern times. We shall here note the following:

Genus Anguilla, Thunberg and Shaw. Eels in general, as distinguished from *Murænæ*, are characterised by the possession of pectoral fins, under which the branchial aperture opens; their swimming bladder has an elongated shape, and near its middle a peculiar glandular body; their stomach has a long cul-de-sac; their intestine is almost straight.

The more restricted genus Anguilla, or *eel properly so called*, has the dorsal and caudal fins continued around the tail, giving it a pointed form.

In the *true* eels, the dorsal begins a considerable distance behind the pectorals. Some have the upper jaw shorter than the lower; such as the *Anguilla vulgaris*, or common eel. (Plate CCCVI. fig. 1.) This fish is universally distributed, and scarcely requires description. The usual colour is an olive tint above, and a silvery colour below; but in some instances the back is spotted with brown. We have observed these fish in considerable numbers leaving fresh-water lakes in the night time, and frequenting meadows, seemingly for the purpose of preying on slugs and snails. They easily move on the land, with a motion resembling that of snakes. The eel grows to the size of two or three feet, and is sometimes said to reach five or six feet in length. It abounds in many European rivers. Eels are caught in immense numbers in the rivers emptying themselves into the Baltic; and they form a considerable article of trade. Two thousand are stated to have been caught at one sweep in Jutland; and in the Garonne 60,000 were taken in one day by a single net.

"That eels migrate towards brackish water," observes Mr Jesse, "in order to deposit their roe, I have but little doubt, for the following reasons. From the month of November until the end of January, provided the frost is not very serious, eels migrate towards the sea. The Thames fishermen are so aware of this fact, that they invariably set their pots or baskets with their mouths up stream during those months, while later in the spring and summer they are set down stream. The best time, however, for taking eels, is during their passage towards the sea. The eel-traps, also, which are set in three different streams near Hampton Court (the contents of which, at different times, I have had opportunities of ex-

[1] *Linn. Trans.* vol. i. p. 187, pl. xvii.

[2] *Règne Animal*, t. ii. p. 348.

amining), have invariably been supplied with eels sufficiently large to be breeders, during the months I have mentioned. This migratory disposition is not shown by small eels; and it may therefore be assumed that they remain nearly stationary till they are old enough to have spawn. I have also ascertained that eels are taken in greater or lesser numbers during the months of November or December, all the way down the river to the brackish water. From thence the young eels migrate, as soon as they are sufficiently large and strong to encounter the several currents of the river, and make their way to the different contributary streams. I have also been able to trace the procession of young eels, or, as it is called here, the *eel-fair*, from the neighbourhood of Blackfriar's Bridge, as far up the river as Chestrey, although they probably make their way as far, or farther than Oxford. So strong, indeed, is their migratory disposition, that it is well known few things will prevent their progress, as, even at the locks at Teddington and Hampton, the young eels have been seen to ascend the large posts of the flood-gates, in order to make their way, when the gates have been shut longer than usual. Those which die stick to the posts; others, which get a little higher, meet with the same fate, until at last a sufficient layer of them is formed to enable the rest to overcome the difficulty of the passage. A curious instance of the means which young eels will have recourse to, in order to perform their migrations, is annually proved in the neighbourhood of Bristol. Near that city there is a large pond, immediately adjoining which is a stream. On the bank between these two waters a large tree grows, the branches of which hang into the pond. By means of these branches, the young eels ascend into the tree, and from thence let themselves drop into the stream below, thus migrating to far distant waters, where they increase in size, and become useful and beneficial to man. A friend of mine, who was a casual witness of this circumstance, informed me that the tree appeared to be quite alive with these little animals. The rapid and unsteady motion of the boughs did not appear to impede their progress."[1]

"All authors agree," adds Mr Yarrell, "that eels are extremely averse to cold. There are no eels in the arctic regions, none in the rivers of Siberia, the Wolga, the Danube, or any of its tributary streams. It is said there are no eels in the Caspian or Black Seas, but they abound in the Mediterranean; and M. Risso has described eight species in his work on the Natural History of the Environs of Nice. There is no doubt, also, that fishes in general, and eels more particularly, are able to appreciate even minute alterations of temperature in the water they inhabit. The brackish water they seek to remain in during the colder months of the year, is of a higher temperature than that of the pure fresh water of the river, or that of the sea. It is a well-known law in chemistry, that when two fluids of different densities come in contact, the temperature of the mixture is elevated for a time, in proportion to the difference in density of the two fluids, from the mutual penetration and condensation. Such a mixture is constantly taking place in rivers that run into the sea, and the temperature of the mixed water is accordingly elevated."[2] As eels are well known to breed in ponds, it may be inferred that their descent to the brackish water, though customary, is not indispensable. They sometimes attain a great size. The species (or variety) called the *sharp-nosed silver eel* has been taken near Cambridge of the weight of twenty-seven pounds.

Some authors make a separate division of the Congers (*Conger*, Cuv.), which chiefly differ from the common eels in having the upper jaw the longest, and the dorsal fin commencing almost over the pectorals. The chief species are the following: *Anguilla conger* (Plate CCCVI. fig. 3) grows to the size of six feet or more, and is as thick as a man's leg. The conger is found around all our coasts. The skin has a leaden hue above, and is white below, with darker spots along the sides. The dorsal is bordered with black. The teeth are sharp, and when captured the fish is capable of giving very severe bites. The fishermen are stated also to dread injury to their legs from a large conger twining round them. It has been said to attack swimmers by coiling round them, and preying on their bodies. It is voracious, and has not unfrequently been found within the carcasses of dead animals, on which it was evidently feeding. The conger fishery was at one time of some consequence on the Cornish coasts, for the supply of Spain and Portugal. The fish were cured by drying, during which they lost much fat. *Anguilla myrus* (Rondelet) has a sharp snout, a thin roundish body of a dark colour, without spots, except toward the head, where a few yellowish dashes are seen; as also a whitish transverse band on the occiput, and two rows of small specks on the back of the neck. This species occurs in the Mediterranean, as do several other small congers, such as *A. balearica*, *mystax*, and *nigra*. The last named lives among the rocks near Nice, and attains to the weight of forty pounds. Its flesh is more esteemed than that of the common kind.

The Genus Ophisurus, or *snake-tail*, differs from the eels properly so called, by the dorsal and ventral fins terminating abruptly before reaching the extremity of the tail, which is thus deprived of fin, and ends in a sharpened point. The intestine resembles that of the eels; but a portion of it extends into the tail, farther back than the anus. The teeth are sharp and cutting. *Ophisurus serpens* is a Mediterranean species, marked by a triple chain of large, dark-brown, oblong spots, on a silvery-white body. It grows to the length of six feet, and is as thick as the human arm. The snout is sharp; the branchial membrane has twenty rays. *Ophisurus guttatus*, a handsome species from Guyana, belongs to this subdivision; as does *O. ophis*, the *Muræna ophis* of Bloch. In some Ophisuri the pectoral fins are small, and sometimes almost imperceptible; a circumstance which assimilates them to the *Murænæ*. Such are *O. colubrinus*, *fasciatus*, and *maculosus*.

Genus Muræna, Thunberg. The species were united by Linnæus to the eels; but they are distinguished sufficiently by the total want of pectoral fins. Their branchial apertures are minute lateral holes; their opercles are so small, and their branchiostegous rays so slender, and so concealed within the skin, that some able naturalists have denied their existence in this genus. Their stomach is a short pouch; and their swimming bladder is small, oval, and placed towards the upper part of the abdomen. Some of them have the dorsal and anal fins distinctly visible; some have obtuse, others sharp cutting teeth, and the latter can bite severely.

The best known is *Muræna Helena*, or *Roman muræna* (Plate CCCVI. fig. 2), which abounds in the Mediterranean, and was introduced by the luxurious Romans of antiquity, in crystal vases, to the table before being cooked, that the guests might admire its variegated skin. This fish is very voracious, and feeds on all sorts of animal matter. The Romans fed them in ponds, and Pliny has recorded the atrocities of Vedius Pollio, who used to punish his offending slaves by throwing them alive to his murænæ. We have seen this fish repeatedly taken at

[1] *Gleanings in Natural History*, second series.

[2] *Ibid.*

Malacopterygii Apodes. Anguilliformes.

Gibraltar, between three and four feet in length. The skin is beautifully marbled with yellow sub-angular markings on a rich brown ground. When captured in nets it lives long out of the water, and is capable of biting very severely, from the sharpness of its numerous teeth. A very beautiful muræna with obtuse teeth, *M. catenata*, is found in the rivers of Guyana; its colours are brown and white. In the same region is found *M. zebra*, a species beautifully marked, on a dark-brown ground, with transverse, linear, distant bands, meeting irregularly beneath. Other species are, *M. reticularis*, *M. punctata*, *M. unicolor*, *M. Haüy*, *M. picta*, *M. meleagris*, *M. grisea*, *M. afra*, *M. stellata*, *M. undulata*, *M. sordida*.

Genus Sphagebranchus, Bloch. This genus differs from *Murœna* chiefly in having the branchial apertures close together, and beneath the throat, instead of being on each side of the neck. The snout is sharp, and projecting far beyond the mouth; the dorsal and anal fins, when perceptible, do not commence until within one third of the length of the fish from the extremity of the tail. Some of them have no appearance of pectoral fins; others have slight vestiges of those parts. One of them, *Sph. cœcus* (Genus *Apterichtes*, Dumeril), is absolutely without any fins at all. The stomach has a long cul-de-sac; the intestine is straight; and all have a long narrow swimming bladder placed towards the posterior extremity.

The best known is *Sphagebranchus rostratus*, first noticed by Bloch. It grows to a length of nine inches. *Sph. imberbis* was described by Laroche in *Ann. du Mus.* xiii. as well as *Sphag. cœcus*, which he considered as a muræna.

Genus Synbranchus, Bloch. This division is distinguished from the last by having only a single branchial orifice, which is placed under the throat, and communicates with the gills on each side. The fishes included in it are totally without pectorals, and their vertical fins are almost entirely adipose. Their head is thicker than any part of the body, and short; the mouth is wide, lips fleshy, teeth small, conical, and in several rows. Their opercles are partly cartilaginous; their branchial rays are very strong; their swimming bladder is long and narrow. They have no cæca to the intestine, which is straight, and can scarcely be distinguished from the stomach except by a kind of pyloric valve. The species inhabit the seas of the hotter parts of America, especially Surinam. Two only are known, *Synbranchus marmoretus* (Plate CCCVI. fig. 4) and *Syn. immaculatus*. They have much the habit of water-snakes.

In succession to the preceding generic subdivisions of the Linnæan *Murænæ*, Cuvier places a singular and recently discovered species, the *Saccopharynx flagellum* of Dr Mitchell. Its body is capable of great inflation. It is a large and voracious fish, measuring about six feet in length, with a deep cleft mouth armed with sharp teeth. It has hitherto been found only in the Atlantic Ocean, where it floats on the surface by means of the inflation just alluded to.[1]

Genus Gymnotus, Linn. The gymnotes, like eels, have the gills partly shut up by a membrane, which, however, opens before the pectoral fins; the anus is placed near the head; the anal fin runs along nearly the whole under part of the fish, and generally reaches to the extremity of the tail, but is not continued along its upper portion.

In Gymnotus, Lacép. *properly so called*, the skin is without visible scales; the intestine, in several convolutions, occupies but a moderate space, and has many cæca; the stomach is a short, blunt sac, with numerous rugæ within. Some of them have two swimming bladders; the anterior is ovate and bilobular, and lies on the œsophagus, at the top of the abdomen; the posterior is cylindrical, and occupies a sinus in the abdominal cavity. The true gymnotes are confined to the rivers of America. The best-known species is *Gymnotus electricus*, or electric eel (Plate CCCVI. fig. 5). This animal has been well described by Dr Garden of Charlestown, by John Hunter, and by Humboldt. It is remarkable for the violence of its electric shocks, which are often so powerful as to stupify a man or a horse. The researches of Hunter detected an organ in the posterior part of this fish, resembling the electric apparatus of the torpedo. See Plate CCCVI. fig. 6. This organ consists of four longitudinal fasciculi, which occupy one half the thickness of the part in which they occur, and about one third of the whole animal. The larger pair lie above, the smaller below. Each fasciculus is composed of flat partitions or septa, with transverse divisions between them. The outer edge of the septa appear in nearly parallel lines in the direction of the longitudinal axis of the body, and consist of thin membranes, which are easily torn; they serve the same purpose as the columns in the analogous organ of the torpedo, making the walls or abutments for the perpendicular and transverse dissepiments, which are exceedingly numerous, and so closely aggregated as to seem almost in contact. The minute prismatic cells, intercepted between these two sorts of plates, contain a gelatinous matter; the septa are about one thirtieth of an inch from each other, and one inch in length contains a series of 240 cells, giving an enormous surface to the electric organs. The whole apparatus is abundantly supplied with nerves from the medula spinalis; and these nerves are seen coming out in pairs from between the vertebræ. In their course they give out branches to the muscles of the back, and to the skin of the animal. In the gymnote, as in the torpedo, the nerves supplying the electric organs are much larger than those bestowed on any part for the purposes of sensation or movement. Hunter thinks, however, that these nerves are more considerable in point of size in the torpedo than in the gymnote. These organs are attached loosely to the muscles of the back which lie between the larger, and they are immediately connected with the skin by a loose cellular texture. Humboldt has given a very interesting and lively description of the mode of capturing the electric gymnote, as practised in South America, near the town of Calabozo.

These fish abound in the stagnant pools of that vicinity. The Indians are well aware of the danger of encountering the gymnote when its powers are unexhausted. They therefore collect twenty or thirty wild horses, force them into the pools, and when the fish have exhausted their electric batteries on the poor horses, they are laid hold of without difficulty. The horses at first exhibit much agitation and terror; they are prevented leaving the pool by an enclosing band of Indians, who goad them with bamboos whenever they attempt to escape. "The eels," says Humboldt, "stunned and confused by the noise of the horses, defended themselves by reiterated discharges of their electric batteries. For some time they seemed likely to gain the victory over the horses and mules; these were seen in every direction, stunned by the frequency and force of the shocks, to disappear under water. Some horses, however, rose again, and, in spite of the active vigilance of the Indians, gained the shore, exhausted with fatigue; and their limbs being benumbed by the electric explosions, they stretched themselves out upon the ground." "I remember the superb picture of a horse entering a cavern,

[1] *Ophiognathus ampullaceus* of Mr Hardwood, *Phil. Trans.* 1827, seems to pertain to the same genus.

and terrified at the sight of a lion. The expression of terror is not there stronger than what we witnessed in this unequal conflict. In less than five minutes two horses were already drowned. The eel, more than five feet long, glides under the belly of the horse or mule; it then makes a discharge from the whole extent of its electric organs, which at once attacks the heart, the viscera, and especially the gastric plexus of nerves." "After this commencement, I was afraid that the sport might end very tragically. But the Indians assured us that the fishing would soon be finished, and that nothing is to be dreaded but the first assault of the gymnotus. In fact, whether the galvanic electricity is accumulated in repose, or the electric organ ceases to perform its functions when fatigued by too long-continued use, the eels, after a time, resemble discharged batteries. Their muscular motion is still equally active, but they no longer have the power of giving energetic shocks. When the combat had lasted a quarter of an hour, the mules and horses appeared less affrighted; they no longer bristled up the mane, and the eye was less expressive of suffering and of terror. They no longer were seen to fall backwards; and the gymnotes, swimming with the body half out of the water, and now flying from the horses instead of attacking them, began themselves, in their turn, to approach the shore."

The electric gymnote is by no means fierce or voracious; but its electric organs are the instruments by which it procures its prey, and defends itself against alligators and other enemies.

It has been several times brought alive to Europe, and some experiments have been made on its electricity,—which is conducted and insulated by the same substances as common galvanism.[1]

So common is the gymnotus in some parts of South America, that, in the neighbourhood of Uritucu, a route at one time much frequented has been entirely abandoned, in consequence of the necessity of fording a stream, in which many mules were killed every year by these subaqueous electric shocks.

The only other known species of gymnotus is the *G. æquilabiatus* of Humboldt, which appears to differ from the other in wanting the posterior swimming bladder.

The Genus Carapus was separated by Cuvier from the gymnotes, with which they were formerly confounded; and the species are distinguished by a scaly compressed body and a slender tail. The appellation is derived from their Brazilian name. All the species live in the rivers of South America, or on the coasts of that country. *Carapus macrourus* grows to the length of eighteen inches or two feet, and is of a brown colour, with small eyes, and slender tail. *C. brachiurus vel fasciatus* is marked with darker transverse bands. *C. albus* is of a whitish colour; tail naked for about an inch; upper lip with a lobule on each side; several pores on the sides of the head. *C. rostratus* has a body like that of *C. macrourus*, but the snout is narrow, compressed, and tubular, with connate jaws; colour pale brown, variegated with darker spots; the scales not visible.

The Genus Sternarchus of Schneider was so denominated from the anus being near the sternum. The anal fin ends before it reaches the extremity of the tail, which has a fin of its own; but the most singular character in the structure of this fish consists of a soft fleshy filament, concealed in a furrow on the dorsum, beyond the middle of the back, and retained in this groove by tendinous threads, which admit of its having some motion; a very singular organ, of which we cannot conjecture the use. The head is oblong, naked, and compressed; neither opercula nor branchial rays are externally visible; the rest of the body is scaly; the teeth are soft, short filaments, like velvet, on the middle of each jaw. The only species is *Sternarchus albifrons*, which was considered by Pallas, its first describer, as a *Gymnotus*.

Genus Gymnarchus, Cuv. Body scaly and elongated, gills but slightly open in front of the pectorals, as in Gymnotus, but the back is furnished all along with a soft rayed fin; there is no fin behind the anus, nor beneath the tail, which has a pointed termination. The head is conical, naked,—the mouth small, and provided with a single row of small cutting teeth.

Gymnarchus Niloticus of Cuvier, discovered by M. Riffault, is, as its name implies, an Egyptian fish, and is, we believe, the only known species.

Genus Leptocephalus, Pennant. This genus differs from the eels by being greatly compressed laterally, by a larger branchial aperture opening before the pectorals, by a head extremely small, and a pointed snout. The pectorals are almost invisible; the dorsal and anal are very small, and unite at the point of the tail. The intestines occupy a narrow line along the inferior margin of the body.

Only one species is known, a native of our own seas, first described by Pennant. It is the *Leptocephalus Morrisii*, a small fish of four inches long by one tenth of an inch in thickness, and so transparent as almost to exhibit the form of the vertebræ, which may also be felt through the integuments. This singular creature was first seen near Holyhead by Mr William Morris, who transmitted it to Pennant. Though still a rare species, it has since been observed by several other British naturalists.

Genus Ophidium, Linn. This genus has the anus far behind; the dorsal and anal fins join in a point at the tail; the body is long and compressed, and covered with small irregular scales, scattered in the thickness of the skin. But these fish differ from eels, in having open gills, furnished with a large operculum, and a branchiostegous membrane, with short rays. The dorsal rays are articulated, but not branched.

The genus is subdivided into two sub-genera, viz. *Ophidium proper*, in which the throat is provided with two cirrhi adhering to the point of the os hyoides. The best-known species is *Ophidium barbatum*, which grows to eight inches; general colour silvery, but the vertical fins banded with black; the surface smooth, scales attached by their centre to the skin; two bifid cirrhi on the throat; skin spotted with small red spots. The swimming bladder is oval, large, and thick, for the size of the fish, and is supported by three peculiar bones suspended under the first vertebra, and moveable by particular muscles. This fish abounds in the Mediterranean, where it is in request as an article of diet. *Ophidium Vassali* is a small species, also found in the Mediterranean; but in the South Seas a large species has been caught. It is named *Oph. blacodes*. Enchelyopus (Fierasfer), Klein, differs in wanting the beards of the true Ophidium. The dorsal fin is so slight as only to seem a fold of the skin; the swimming bladder has but two supporting bones. Only one species is recognised, *Ophidium imberbe* of Linn., which is also *Gymnotus acus* of several naturalists. As a British species, it was first communicated to Pennant by the Duchess of Portland, from Weymouth. It has since been found by Montagu on the south coast of Devon.

[1] Dr Traill informs us that he had two sent to him from Demerary, but they died the day before the ship made the coast of England, and were unluckily thrown overboard.

Genus Ammodytes, Linn. Has a thin and elongated form. The dorsal fin is furnished with articulated rays, but is simple for a considerable part of its extent. There is a second fin behind the anus, and a third at the end of the tail, which is forked. These three fins are quite distinct, or separate from each other. The snout is pointed; the upper jaw susceptible of extension, but the lower is longer than the upper when the latter is not extended. The stomach is angular and fleshy; there is no swimming bladder nor cæca. Only one British species is as yet distinctly known, the *Ammodytes tobianus* (our common launce), a fish about eight or ten inches long, the body somewhat of a square form, but the angles not sharp, and the sides slightly convex. It is very frequent on our sandy coasts. Its back is bluish, the rest rich silvery. This fish lives on vermes and other marine animals, which it is believed to pursue by burrowing in the sand, from whence it is often dug up at the depth of a foot. It is prized as food, and is considered as an excellent bait for turbot and mackerel. It is the favourite prey of the latter fish; and the porpoise ploughs up the sand at the bottom of the sea with his nose, in the manner of a hog, in search of this species, which has often been found in his stomach. It is also sought for by salmon, which have been captured in the sandy bays of Sutherland, by means of a hook baited by a launce, commonly called the *sand-eel.*

It is extremely probable that two British species are usually confounded by us under the name of launce.[1]

The various genera of fishes with which we have been hitherto engaged, not only possess an osseous or fibrous skeleton, and free and complete jaws, but their branchiæ are constantly pectiniform, that is, in the shape of laminæ or combs. We now proceed to others, in which the respiratory organs assume another form.

ORDER V.—LOPHOBRANCHII.

Jaws complete and free, as in the preceding orders, but the branchiæ, instead of being comb-shaped, are divided into little rounded tufts, disposed in pairs along the branchial arches. The branchiæ have this further peculiarity, that they are entirely enclosed beneath a large operculum, attached all round by a membrane, which permits the water to escape merely through a small hole, and exhibits only vestiges of rays.

The genera of this order may be distinguished externally by the *cuirassed* aspect of their bodies, which are strongly plated, very angular, and frequently furnished with spiny projections. The species are meagre creatures, of small size, and very extraordinary aspect. They have scarcely any *flesh* upon their bones. The intestine is uniform, and without cæca; the swimming bladder is thin, but tolerably large in proportion to the other parts. The order is almost entirely composed of the old genera *Syngnathus* and *Pegasus* of Linnæus.

The genus Syngnathus of the great Swedish naturalist consisted of a rather numerous assemblage of species, distinguished by a tubular muzzle, formed, like that of the Fistularidæ, by a prolongation of the ethmoid, vomer, and tympanic bones, of the pre-opercles, sub-opercles, &c. and terminated by a mouth of the ordinary kind, but almost vertically cleft. The respiratory opening is towards the nape of the neck, and the ventral fins are wanting. The generative system is characterised by this peculiarity, that the eggs slip into, and are hatched in, a kind of sac or pocket, formed by a pursing of the skin—in some beneath the belly, in others at the base of the tail. This pouch opens in due time for the escape of the young. In this respect, then, these fishes may be said to connect the osseous with the cartilaginous kinds, for the eggs are hatched internally, and the young are produced alive. This fact was observed by Aristotle, and has lately been confirmed (so far, at least, as concerns *S. acus*) by Cavolini. The genus is now subdivided into three minor groups, as follows:—

1*st*, Genus Syngnathus properly so called. Body very long, thin, and differing but little in its diameter throughout. Several species occur in all our seas. They differ in the character and number of their fins.

2*d*, Genus Hippocampus, Cuv. Body laterally compressed, and obviously higher than at the tail. The surface is raised into ridges, its edges are angular and incised, and the hinder parts of the body and tail have the appearance of being divided into segments. The caudal fin is wanting.

Of this genus several species are found in the European seas, and one or two occur along the British shores. The greater number, however, are exotic. In the dried specimens the head is usually bent at right angles with the body, the thorax curved, and the tail bent inwards. From the peculiar aspect which they exhibit in this condition, they have received the name of *sea-horses.* The most remarkable species with which we are acquainted is the *Hippocampus foliatus* of Shaw, or foliated pipe-fish. (See Plate CCCVI. fig. 7.) This rare and very singularly constructed fish is a native of the Southern Ocean. The specimen described by Shaw was transmitted from New Holland to Sir Joseph Banks. The one here figured was sent to Professor Jameson from Van Diemen's Land. We should not have hesitated to consider this species as synonymous with *S. tæniolatus* of Lacépède (and the more readily as they seem to be regarded as identical by Cuvier[2]); but on comparing it with the figure in the *Annales du Mus.* we find that the Van Diemen's Land specimen possesses two large appendages on the dorsal outline, not represented by the author of the earlier *Hist. Nat. des Poissons.*

3*d*, Genus Solenostoma, Seb. and Lacép. Differs from *Syngnathus* chiefly in possessing very large ventrals placed behind the pectorals, and united together and with the body so as to form a kind of apron, which, like the pouch of the genus just named, serves to retain the ova. There is also a dorsal, with few rays, but elevated, and placed near the nape; another very small fin on the origin of the tail; and a large pointed caudal. In other respects the genus bears a great resemblance to *Hippocampus.* There is only a single species known, the *Fistularia paradoxa* of Pallas.[3]

Genus Pegasus, Linn. Projecting muzzle formed by the same pieces as in the preceding genera, but the mouth, instead of being placed at the extremity, is found at the base, and, in its protractile nature, so far resembles that of the sturgeon, although it is composed of the same bones as the mouth of ordinary fishes.

The body in this genus is cuirassed like that of *Hippocampus* and *Solenostoma*, but the trunk is broad, depressed, the branchial opening lateral, and there are two distinct ventral fins behind the pectorals, which are often large and wing-like, and have given rise to the generic name. The dorsal and anal are opposite to each other. The species are chiefly from the Indian seas. See Plate CCCVI. fig. 10.

Plectognathi. Gymnodontes.

ORDER VI.—PLECTOGNATHI.

The fishes of this order approach the great chondropterygian division in the imperfection of their jaws, and the slowness with which their skeleton hardens; yet that skeleton is fibrous, and its general structure resembles that of the ordinary or osseous fishes. The principal distinctive character, however, of the Plectognathi, consists in the maxillary bone being soldered or firmly attached on the side of the inter-maxillary, which alone forms the jaw, and in the palatine arch being connected by suture with the cranium, which consequently renders it immoveable. Moreover, the rays and opercles are concealed beneath a thick skin, which permits only a small branchial cleft to be visible externally. The vestiges of ribs are very slight. The true ventrals are wanting. The intestinal canal is ample, but without cæca, and almost all the species are provided with a rather large swimming bladder.

The order comprises two very natural families, characterised by the different armature of the jaws.

FAMILY I.—GYMNODONTES.

Instead of apparent teeth, the jaws are furnished with a substance like ivory, divided internally into laminæ or plates, the totality of which resembles the beak of a parrot, and is essentially composed of true teeth united together, and succeeding each other as they become used by trituration. The opercles are small, their rays five in number on each side, and the whole greatly concealed. The species live on Crustacea and Fuci. Their flesh is in general mucous, and slightly esteemed. Some indeed are even poisonous, at least during certain seasons.

Two of the genera (*Tetraodon* and *Diodon*), commonly called orbs or balloon-fish, possess a singular faculty of inflating their bodies by swallowing great quantities of air. When thus swollen, they roll over and float upon the surface, belly uppermost, apparently unable to direct their course. They are not, however, defenceless, for the spines with which their skin is armed project in all directions. Their swimming bladder has two lobes, and their kidneys, which are placed very high up, have been sometimes mistaken for lungs. There are but three branchiæ on each side. Each nostril is furnished with a double fleshy tentaculum.

Genus Diodon, Linn. The undivided jaws exhibit but one piece above and another below,—from whence the generic name, which signifies *two teeth*. Behind each cutting edge is a rounded portion, transversely grooved, and forming a powerful instrument of mastication.[1] The skin is armed on all sides by strong, pointed spines, so that, when inflated, these creatures bear a resemblance to a gigantic burr of a chestnut tree.

The species are numerous in the warmer seas. One of the most common is the *Diodon atinga* of Bloch, which measures about a foot in diameter. It inhabits the seas of India, America, and Southern Africa, and feeds on the smaller fishes, Crustacea, and shell-fish, the calcareous covering of which it breaks with great facility, by means of its robust and bony jaws. It is a dangerous species to meddle with, owing to the sudden and hedgehog-like manner in which it bristles up its spines. It seems synonymous with *D. hystrix* of Linn., commonly called the sea-porcupine, and was formerly a frequent and dusty appendage in the shop of the apothecary. (See Plate CCCVI. fig. 8.) *Diodon holocanthus* inhabits almost all the seas between the tropics. When taken by means of a hook, it exhibits the most ungovernable movements,—alternately inflates and compresses its body, ascends and descends with rapidity and violence, and is extremely dangerous to lay hold of. It is fished for both in the Red Sea and along the coast of Japan; and, according to Dutertre, the hooks are baited with Crustacea. The bait, it appears, is first approached with caution, then tasted, left, returned to, and finally swallowed. It no sooner, however, finds itself fairly hooked, than it swells itself up like a balloon, utters a dull sound like that produced by a turkey-cock while making its wheel, and then becomes exceedingly furious. It next has recourse to an opposite mode of action, by lowering its spines, disinflating its body, and becoming as loose and flabby as a wet glove.[2] It resumes its activity, however, as soon as it perceives the fisherman drawing towards it, or feels itself being drawn towards the fisherman. In short it has a particular dislike to being killed.

Genus Tetraodon, Linn. Jaws divided in the centre by a suture, so as to exhibit the appearance of four teeth (from whence the name), two above and two below. The skin is armed merely by small spines, which project but little. Several species are regarded as poisonous.

The most anciently known is an Egyptian species, *T. lineatus*, Linn., which is thrown by the floods in vast numbers over the prolific banks of the Nile, where it is afterwards gathered as a plaything by the children. According to Hasselquist, however, the Egyptians hold it in abhorrence, and believe that the use of its flesh as food is followed by death. The prickles of its skin produce a sensation like the stinging of nettles. In many Mahommedan countries another species, called *T. hispidus* by Lacépède, is fully inflated, then carefully dried, and afterwards suspended from the pinnacle of the minarets, where it serves the purpose of a weathercock. The hare tetraodon, as it is called (*T. lagocephalus*, Linn.), appears to have been described by Pennant under the title of *Globe Diodon*. Though a tropical species, it has occurred occasionally along the British coasts, particularly near Penzance in Cornwall. We here figure a curious Indian species, the *Tetraodon patoca* of Dr Hamilton Buchanan. Plate CCCVI. fig. 9.

Baron Cuvier has separated from the preceding, under the generic title of Orthagoriscus (imposed by Schneider, and synonymous with genus *Cephalus* of Shaw), the peculiar species known to English readers under the name of *sun-fish*, the *Poissons-lunes* of our continental neighbours.[3] The jaws are undivided, as in *Diodon*, but the body, compressed and without spines, is unsusceptible of inflation, and the tail so short, and vertical in its posterior outline, as to convey the idea of an artificial truncation. The form is in consequence extraordinary and characteristic. The dorsal and anal fin, each high and pointed, seem to unite with the caudal. The swimming bladder is wanting, the stomach small, and penetrated directly by the *ductus choledocus*. Beneath the skin we find a thick layer of a gelatinous nature. The European seas produce a species which sometimes measures more than four feet in length, and weighs, in consequence of its bulky proportions, above three hundred pounds. It is of a fine silvery hue, and is named *Tetraodon mola* by Linnæus, and the *short sun-fish* by British writers. (See Plate CCCVI. fig. 11.) It often exhibits during the night a high

[1] Baron Cuvier observes, that the jaws of these fishes are by no means unfrequent among petrifactions.

[2] Griffith's *Animal Kingdom*, vol. x. p. 581.

[3] The title of *Poisson-lune* is however bestowed also on other species by French writers, for example on *Lampris guttatus* of Retzius, which is the *Zeus luna* of Gmelin, and the *Opah* of Pennant.

degree of phosphoric splendour. We once came alongside of one while swimming in the Mediterranean. It got out of our way by sinking very slowly downwards. The *Diodon mola* of Pallas (*Spic. Zool.*) is another species of the same genus.

The only remaining genus of the first family of Plectognathi is named Triodon by Cuvier, from a species discovered in the Indian seas by M. Reinward.[1]

FAMILY II.—SCLERODERMI.

Easily distinguished by the conical or pyramidal form of the muzzle, prolonged from the region of the eyes, and terminated by a little mouth armed with a small number of distinct teeth on each jaw. The skin is generally rough, or covered by hard scales. The swimming bladder is large and robust, and of an oval form.

Genus Balistes, Linn. Body compressed; eight teeth upon a single row on each jaw, and generally of a cutting kind; skin scaly or engrained, but not absolutely osseous; first dorsal composed of one or more spines, articulated on a special bone, which is attached to the cranium, and presents a groove into which the spines are received; second dorsal soft and long, and corresponding in its position to an anal fin of nearly similar form. Although the ventral fins are wanting, we nevertheless perceive in the skeleton a true pelvic bone suspended to those of the shoulder.

The species occur in vast numbers in the torrid zone, among rocks nearly on a level with the surface of the water, where they shine with a brilliant lustre resembling that of the beautiful chætodons, formerly described. Their flesh, at no time much esteemed, is said to become dangerous as food while they themselves are nourished by the polypi of the coral reefs. Cuvier however states, that in such specimens as he had occasion to dissect, he found nothing but the remains of marine vegetation. The generic name is derived from *balista*, an ancient implement of war, to which the inclined dorsal spine has been regarded as bearing some resemblance. In modern times the original genus has been divided into the four following groups.

In Balistes (properly so called) of Cuvier, the whole body is clothed by large, hard, rhomboidal scales, which not being imbricated, or encroaching on each other, present the appearance of compartments on the skin; their anterior dorsal has three spines, of which the first is much the largest, the third being very small, and placed somewhat apart behind. The extremity of the pelvis is always prickly and projecting, and behind it are some spines involved in the skin, which in the lengthened species have been regarded as rays of the ventral fins. Some have no particular armature on the sides of the tail; others have the lateral portion of that part armed by a certain number of ranges of spines curved forwards.

In Monocanthus, Cuv., the scales are very small, and beset by close asperities; the extremity of the pelvis is projecting and spiny, as in the preceding group, but there is only one large dentated spine to the first dorsal, or, if the second exists, it is almost imperceptible.

In Aluteres, Cuv., the body is elongated, and covered by scarcely visible, small, close-set grains; there is a single spine to the first dorsal; and the pelvis is entirely subcutaneous, not forming that spiny projection visible in the other *Balistes*. See Plate CCCVI. fig. 12.

In Triacanthus, Cuv., the species are distinguished by possessing a kind of ventral fins, each sustained by a large single spiny ray, and adhering to an unprojecting pelvis. The first dorsal, posterior to its principal spine, has three or four smaller ones. The skin is covered by small, close-set scales, and the tail is more elongated than in the other groups. There is only one species known, a small fish from the Indian seas, figured by Bloch (148, 2) under the name of *Balistes bi-aculeatus*.

Genus Ostracion, Linn. Instead of scales, the species of this genus have the head and body covered by regular and bony compartments, soldered together so as to form an inflexible cuirass, which leaves nothing moveable but the tail, fins, mouth, and a small lip which borders the gills. The majority even of the vertebral joints are also as it were soldered. Each jaw is armed with from ten to twelve conical teeth. The branchiæ open only by a small cleft, furnished with a cutaneous lobe; but internally they are provided with an opercle and six rays. Both the pelvic bones and ventral fins are wanting, and there is only a single dorsal and anal fin, each small of its kind.

These anomalous-looking fishes are sparingly supplied with flesh; but their liver is large, and yields an abundant supply of oil. Some are suspected of being poisonous. The species are called *trunk-fish* by our English writers. We here figure the horned trunk-fish, *Ostracion cornutus* of Linn. and Bloch, a native, like most of the genus, of the Indian and American seas. Plate CCCVI. fig. 13.

SECOND GREAT SERIES OF THE CLASS OF FISHES.

THE CHONDROPTERYGII, OR CARTILAGINOUS FISHES.

This division of fishes, by the peculiarities of the organs of hearing and generation in some genera, approaches to the class of reptiles; while others have a skeleton so defective, and such simplicity of organization, that we might almost arrange them with Vermes. We may thus consider them, says Cuvier, as bearing the same relation to the first series as the marsupial animals do to the other mammifera furnished with claws.

Their skeleton is distinctly cartilaginous, destitute of true bony matter, as the calcareous portion is not disposed into a fibrous structure, but is deposited in grains in a substance essentially gelatinous. The skull is composed of a single piece, and consequently is destitute of sutures, but possesses foramina, prominences, and fossulæ, like the cranium of other fishes. The facial articulations are also wanting; and it forms one of their characteristics to want the maxillary and inter-maxillary bones, which ordinarily support the teeth of the upper jaw; or they have only vestiges of these parts, while their functions are performed by bones analogous to the palatines or the vomer. In some the vertebral column, as in the lamprey, forms but a single piece; in others, as in certain rays, several vertebræ are joined together. The gelatinous inter-vertebral substance, which in other fishes communicates from one to another through a small foramen, is in several of this series a cord of equal thickness, perforating all the vertebræ. Yet their nervous system, connected with the organs of digestion, is as complete as in other fishes; and some of them have organs of copulation and generation quite as perfect as in the class of reptiles.

This series is divided into two orders; one distinguished by having the gills free, as in other fishes; the other with fixed branchiæ.

---

[1] See *Règne Animal*, t. ii. p. 370; and Duperrey's *Voyage*, *Poissons*, No. 4.

ORDER I.—STURIONES, OR CHONDROPTERYGII WITH FREE BRANCHIÆ.

The few genera of this order approach to ordinary fishes, by their gills being attached only at one extremity. They have but one branchial aperture, which is very open; they have but one operculum, and are without rays to the membrane of the gills.

Genus Acipenser, Linn.; Sturgeon. The general form of this genus resembles that of the sharks; but they are distinguished by longitudinal rows of bony plates or bosses implanted on the skin; the head is defended by similar plates; the mouth is small, and, as in sharks, placed below the snout; the palatal bones are united to the maxillaries, and vestiges of the inter-maxillaries may be traced in the lips, while the mouth is capable of some degree of projection, by its position on a style with three articulations. Instead of teeth, the mouth is furnished with a sort of horny process on the jaws. The nostrils and eyes are on the sides of the head; the muzzle is furnished with vermiform cirrhi. There is no vestige of an external ear, but the labyrinth is perfect within the bones of the head. The dorsal fin is behind the ventrals, and the anal immediately below the dorsal. The caudal fin surrounds the extremity of the spine, and its upper lobe is longer than the lower. Internally there exists the spiral intestinal valve, and the pancreas forming a single mass; but we also find a very large and strong swimming bladder, communicating by a wide aperture with the gullet. They prey on the smaller fishes, in pursuing which they can exert much speed; but in the rivers they frequent they are said to search for Vermes in the oozy bottom, which they explore with their snout, like swine.

Sturgeons are marine fishes, but at certain seasons they ascend in vast numbers particular rivers, where they are the subject of extensive fisheries, particularly in the large rivers that disembogue themselves into the Black Sea and Caspian, and the rivers of France and Prussia; they abound also in the large rivers of North America, where the species appear to be peculiar to that continent.

The European species are—

Acipenser sturio, or common sturgeon. Its ordinary length is seven or eight feet, but sometimes they are caught exceeding sixteen feet. Snout pointed, and furnished with cirrhi; body gradually tapering, pentagonal, from the disposition of six longitudinal rows of hard, bony, radiated, and mucronated tubercles. Its skin, except the flat belly, is rough, from small plates of a similar form; mouth a transverse oval orifice; lips cartilaginous; tongue thick; gill-covers consisting of an oval radiated plate; pectorals oval; dorsal near the tail. Its flesh is white and delicate, resembling veal. Its roe forms common *caviar*. This fish was highly prized by the ancients, and is still an esteemed food.

Acipenser ruthenus, or sterlet, is the smallest of European sturgeons, rarely measuring more than three feet long. It is very numerous in the Volga and Ural, and is uncommon in the Baltic. The lateral tubercles are very numerous, and strongly carinated; those of the under part of the body are more flattened. The flesh resembles delicate veal, and the roe forms the most highly prized *caviar*. See Plate CCCVII. fig. 1.

Acipenser huso, or isinglass sturgeon, is the largest of the genus, sometimes attaining the length of from twenty to thirty feet, and weighing from 1500 to between 2000 and 3000 lbs. Its skin is much less tuberculated than the common sturgeon, and is covered with a viscid mucus; the snout and cirrhi are shorter. This species is chiefly found in the Caspian and Euxine, or the rivers that flow into those seas; but the large sturgeons sometimes caught in the northern seas appear also to belong to the same species. The best isinglass is formed of its air-bladder.

The following species, which are found in the rivers of North America, appear to be peculiar to that continent (See *Amer. Trans.* vol. i.): *Acipenser brevirostris*, *A. oxyrhynchus*, *A. maculosus*, and *A. rubicundus*. The last of these appears to be the American representative of the *A. ruthenus*, the preceding one of the *A. sturio*.[1]

Genus Polyodon, Lacép.; Spatularia, Shaw. This genus, which consists but of a single species, is at once recognised by the enormous prolongation of its snout, which has a dilated middle, something resembling the leaf of a tree when viewed from above. The habit of the body resembles the sturgeon; but the spinal column is formed of one piece, as in the lamprey. The upper jaw is formed of the maxillary and palate bones united together, and the pedicle of the mouth has two articulations; the mouth is small, and furnished with numerous minute teeth. The spiracle is wide, and covered by a very large, soft operculum, extending to the middle of the body. The intestine is provided with the spiral valve, so frequent among the Chondropterygii; but the pancreas exhibits the commencement of a subdivision into lobules. The existence of an air-bladder sufficiently distinguishes it from the *Squali*. It has only been found in the Mississippi, and does not exceed a foot in length.

Genus Chimæra, Linn. This genus has a strong affinity to the Squali in general shape, and in the position of the fins, but the gills have only one aperture on each side; yet, on inspecting more accurately, we see that the rays are attached by most of the edges, and that there are really five holes opening into the bottom of a general cavity. A rudiment of an operculum is found in the skin; the jaws are still less complex than in the Squali, for the upper jaw is represented only by the vomer, and the palate bones and tympana are merely rudimentary, attached to the sides of the muzzle. Instead of teeth, the mouth is furnished with undivided hard plates, of which four are above and two below. The snout resembles that of the shark, and also has regular ranges of pores. The first dorsal fin is armed with a strong spine, and is placed over the pectorals. The males, as in the Squali, are distinguished by the cartilaginous appendages of the ventral fins, divided into three branches, and have two spiny plates before the base of the ventrals. These fish have also on their front a fleshy caruncle, garnished with a group of small prickles. The intestine of this genus is short, and has a spiral valve. The female lays eggs of a large size and coriaceous consistence, flattened, and hairy. The only species is *Chimæra borealis*, or northern chimera. It is found in the Northern Ocean, where it is believed to feed on the numerous Mollusca and Crustacea of that sea. It is rarely taken, because it keeps much in deep water; but it has been occasionally caught among our northern islands, and is sometimes seen of the length of three or four feet. Its head is the thickest part of the body, whence it tapers uniformly to the tail. It is most common on the coasts of Norway, where its eggs are eaten, and the oil of its liver is used as a stimulant embrocation. It also occurs in the Mediterranean.

Genus Callorhynchus, Gronovius. Cuvier separates this from the last genus, to which it was united by Linnæus. It is distinguished by its snout terminating in a fleshy,

[1] In a quarto work published some time ago at Berlin (*Gettreue Darstellung*, &c.), containing figures and description of the various animals of use in Therapeutics, there is a *Monograph of the Sturgeons* by Messrs Brandt and Rutzeburgh. See *Annales des Sciences Nat.* for Feb. 1831, p. 223.

flattened process, something in the form of a hoe. The mouth is small, and below the snout. The second dorsal fin commences over the ventrals, and terminates opposite to the commencement of the lower part of the tail. The only known species inhabits the Southern Ocean. See Plate CCCVII. figs. 2 and 3.

ORDER II.—CHONDROPTERYGII WITH FIXED BRANCHIÆ.

Instead of having the gills free at their external edge, in this order we find them fixed all round; and in respiration water is emitted through as many apertures as there are intervals between the rays. Another peculiarity of this order consists in the small cartilaginous arches suspended from the soft parts at the outer edge of the branchiæ.

The Linnæan genera *Squalus* and *Raia* are the principal members of this order; but Cuvier and the later Ichthyologists have subdivided these into several genera, according to marked peculiarities in their anatomical structure.

FAMILY I.—SELACHII, OR PLAGIOSTOMI.

The palatal and post-mandibular bones support the teeth, while the bones corresponding to the jaws in other fishes are merely rudimentary. A single bone connects these jaws with the cranium, and represents at the same time tympana, jugal, and temporal bones. The os hyoides is attached to a single pedicle, and, as in ordinary fishes, supports the rays of the gills. The labyrinth is membranous, and included in the cartilaginous substance of the cranium; the sac attached to it does not contain, as in fishes, the porcelanous concretions, but masses that are easily pulverized. The pancreas has the form of a conglomerate gland. The intestinal canal is short; but one part of the tube is furnished internally with a spiral lamina, that seems intended to prevent the too rapid passage of the food.

The Selachii have pectoral and ventral fins; the latter placed behind the abdomen, and on the sides of the anus.

In some respects their sexual intercourse resembles that of Mammifera. The females have well-developed oviducts, which serve the purpose of a matrix in the species whose young are perfected within the body; while in others the ova are covered by a tough and horny envelope, to the formation of which a large gland surrounding each oviduct is subservient. These eggs, especially in the *Squali*, have the form of a parallelogram with long filamentous tendrils at each corner, intended for attaching the egg to Fuci or sub-marine rocks during the maturation of the young included animals. Many of these eggs are found in a female, but only two appear to be perfected at once. In these the fœtus is coiled up, and to its umbilical region is attached a large pyriform bag, of a white colour, by a slender tube. On opening this bag it is found filled with a yellowish, thin liquid, like the yolk of a hen's egg, intended for the nourishment of the fœtus. When the young animal becomes able to collect its own food, the coriaceous egg opens at one end, the creature escapes, and soon the bag, now empty and useless, drops off. The males are provided with two peculiar organs, placed at the inner edge of the ventral fins. Some have supposed that these are *intimately* connected with the generative process; others regard them as mere *holders*, by means of which the female is more closely embraced by the male.

Genus Squalus, Linn.; Shark. This forms the first great genus of our present order. The general form is elongated; the tail is thick, with the spinal column continued into the upper lobe; the pectoral fins are of considerable size; the spiracles are on the sides of the neck; and the eyes on each side of the head. The muzzle is supported by three cartilaginous projections, proceeding from the anterior part of the cranium; and we can easily observe in the skeleton the rudimentary jaws. The scapula is suspended in the flesh behind the gills. Some of the sharks are oviparous, while others are viviparous. Distinct but small branchial rays; there are rudiments of ribs along the spine; and that column is divided into regular vertebræ.

The original genus is numerous, and may be divided as follows.

Genus Scyllium, Cuv. This division is characterised by a short, obtuse muzzle, by nostrils near the mouth, continued in grooves which reach to the edge of the lip, and more or less closed by one or two cuticular lobules. Their teeth have a central point and two lateral prongs. They have spiracles, partly over the pectoral fins. Their dorsal fins are placed far back, the anterior not being before the ventrals. All have an anal fin; and, in some species, its position corresponds to the interval between the two dorsals; the tail is elongated, truncated, not forked.

The most common on our coasts are the following species.

Sq. canicula, L.; greater spotted dog-fish, P. This common and prolific species is very numerous on the northern and western coasts of Britain. The colour of the male is dusky, with numerous distinct small, blackish, spots: the female, of which some naturalists have made another species, is larger than the male, of a more red hue, variegated with deep-brown spots disposed in an ocellated pattern on the sides. The ventral fins of this species have the edge cut obliquely.

Sq. catulus, et Sq. stellaris, are also the male and female of another species not uncommon on our coasts. This species differs from the last in size. The spots on its surface are fuller and broader; the ventral fins are more square at the edge.

To this sub-genus belong several other *Squali*, natives of foreign seas. They are distinguished by the position of the anal fin, which is placed behind the second dorsal; the spiracles are remarkably small; the fifth branchial aperture is often concealed in the fourth, and the lobes of the nostrils are usually prolonged into cirrhi.

Among the species are *Sq. pendulatus; Sq. Isabella*, Shaw; *Sq. cirrhatus*, Linn.; *Sq. lobatus;* and *Sq. tigrinus*, Lacép., or *Squalus fasciatus* of Bloch.

This last is one of the most beautiful of the order, and has been observed of the length of fourteen or fifteen feet, with a large and blunt head, and tapering body. (See Plate CCCVII. fig. 4.) A few years ago one of them was observed for several hours to follow a Liverpool East Indiaman off Madagascar. It was elegantly transversely banded with alternate whitish and dark brown or blackish fasciæ; and was further variegated by ocellated spots or rings on various parts of its body, which seemed to be about fourteen feet long. Its head appeared to be four and a half feet across; but the thickest part of its body did not seem more than two feet in diameter. It was accompanied by several *pilot-fish*, which often swam before, and returned towards it. Several attempts were made to catch it with large baits of fresh meat, but it never ventured to seize one of them. The lower jaw was distinctly visible whenever it opened its mouth, into which the accompanying fishes seemed to the spectators to enter and to leave at pleasure.

Genus Squalus properly so called, Cuv. This group comprehends all those species with a pointed muzzle, under which the nostrils are placed; but the latter parts are not terminated by a groove, nor are they furnished with lobules. The tail has more or less of a forked shape. We may farther subdivide this genus in accordance with the presence or absence of apertures behind the eyes, and of an anal fin.

Without Air-Holes, with Anal Fin.

Carcharias, Cuv. This well-known and numerous group have extremely sharp-pointed teeth, often serrated on their edges. Of these, their jaws are armed with several rows, which they have the power of elevating or depressing, and can use with remarkable effect, from the strength of the muscles moving the lower jaw. The first dorsal fin is considerably before the ventrals, and the second is almost opposite to the anal. The posterior branchial apertures are over the pectoral fins.

The best-known species is *Sq. carcharias*, or white shark, the dread of seamen in hot climates, and not unfrequently seen on our own coasts. It is a very large fish, growing, it is said, to more than thirty feet, and often observed to measure from fifteen to twenty-five feet. The teeth are, in full-grown animals, in six rows; those in the upper jaw are nearly isosceles triangles, with sharp, dentated edges; those in the lower jaw have a narrow lancet-shaped point on a broader basis, with smooth-cutting edges. From the position of the mouth in this species, the animal turns on its side on seizing its prey. Its voracity is well known, and it has been seen to leap out of the water in its eagerness to snatch a suspended morsel. The jaws are so powerful as to bite at once through the body of a man. The gullet is very large, and the intestine short. One killed near Marseilles is alleged to have had the entire body of a man, and several fish, in its stomach; and one captured off the island of St Margaretta is even said to have contained the whole body of a horse. This one had the enormous weight of 1500 pounds.

The sailors believe that the pilot-fish, which is so constant an attendant on this species, directs him to his prey; and, by touching his head, warns him against a baited hook. Certain it is, that the pilot-fish have been repeatedly seen clinging to a shark while he was hoisting on deck, and appeared as if distressed on separation from their formidable comrade, who has never been known, in his utmost voracity, to attack his friendly guides. What the instinct is that produces this attachment is unknown; but probably it depends on the pilot (*Naucrates ductor*) obtaining its subsistence from the remains of the shark's prey, as the jackal does from that of the lion.[1]

Little of the age or development of this species is ascertained. The female has been known to contain many ova; but only three or four are perfected at a time, and impregnation may take place long before the full growth of the animal. A shark ten feet long has been found to contain forty ova, three or four of which were near maturity.

Sq. vulpes, the thrasher, so called from the inordinate length of his tail, which is almost half the length of the animal. It is the upper lobe which is thus elongated; and as it has the fin along its under side, it gives the organ some resemblance to a fox's tail. It grows, even in our own seas, to a large size. Pennant measured one thirteen feet, of which the tail was more than six feet. The body is round, the nose short but pointed; the teeth are small, but sharp.

It is this species which is said to attack various Cetacea, which it harasses by dealing them violent strokes with its tail, when they rise to the surface for the purpose of breathing.

Sq. glaucus, the blue shark, is a very bold and voracious fish, not unfrequent on our coasts during the herring season. It grows to ten, or even fourteen feet in length; is of a slaty blue above, and smoother than the rest of the genus. Head large, muzzle very pointed; mouth large; teeth almost triangular, long, sharply pointed; the upper curvilinear, bent outwards; the lower straighter, and all dentated.

The nostrils are long and transverse. Artedi and others have noticed a triangular fossule, with its apex downward, on the lower part of the back.

To this subdivision we must refer the following species: *Sq. ustus*, Dum.; *S. ocellatus; Sq. ciliaris;* and several Indian species, described by Russel.

Lamna, Cuv. This subdivision is distinguished from the last by having all the spiracles *before* the pectoral fins, and by having a projecting pyramidal snout.

Squalus cornubicus, portbeagle shark, is well known in the Mediterranean and British seas, and is formidable on account of its teeth and size. One caught in 1834, on the coast of Caithness, now in the College Museum of Edinburgh, measures eight and a half feet, and is in girth four feet eight inches. Its teeth are upwards of an inch in length, extremely sharp, but not serrated. There are three rows of teeth, of an elongated form, slightly bent outward, and extremely sharp. The nostrils are under the snout, two and a half inches from the eye.[2] The circumference of the mouth round both jaws is about three feet. This animal is confounded with the white shark, both by seamen and naturalists; but it differs in the form of its teeth, as well as in the other circumstances noticed in the character.

The colour of this species is deep bluish-black, and the skin is smoother than that of most of its congeners.

Sq. monensis, Beaumaris shark, first described by Pennant, was by some considered as a sexual difference only of the last; but this is a mistake. Though similar in many respects, they are quite distinct, as the following characters, taken from a fine specimen caught in Orkney in 1833, will show. The colour of the upper parts a pale leaden gray, the lower parts yellowish white. Skin above covered with very minute granular roughnesses, but less prominent than in the *Squalus catulus* and *Sq.*

---

[1] We have already discussed the point above alluded to, at greater length, in a preceding portion of the present treatise. See p. 185.

[2] The following are the more detailed measurements of the specimen above mentioned:—

	Feet.	Inches.		Feet.	Inches.
Extreme length along curvature of back	8	3	First dorsal, high, along its edge	1	1
Girth at abdomen	4	8	——— perpendicularly	0	10
—— at spiracles	4	0	——— broad	0	9·5
Width of mouth round upper lip	1	9	Second dorsal, high	0	1·8
——— round lower lip	1	4	——— broad	0	1·5
Length of teeth in upper jaw	0	1·5	Pectorals along edge	1	5
——— in lower jaw	0	1·2	——— broad	0	9
Length of muzzle from eye	0	7·5	Caudal, upper lobe	1	10·5
——— from upper lip	0	4·5	——— lower lobe	1	3
Eye in diameter about	0	1	——— spread	2	0
Nostrils from eye	0	2·5	Ventral at outer edge	0	4
Length of spiracles	0	9	From pectoral to ventral	2	4
From snout to first dorsal	3	5·5	Keel near tail	0	9·5
From first to second dorsal	2	6	Anal fin, broad	0	1·5
From second dorsal to caudal	0	0			

canicula. Form of the head obtusely conical, muzzle blunt. The teeth were in three rows, two of which were recumbent, rather than with sharp points and cutting edges, and two small processes at the bases of those of the lower jaw. Numerous nasal pores were perceived on the snout, six of which on each side admitted a slender probe to the depth of three inches; but there were no temporal apertures. A deep sulcus, eight inches long, extended from the ventrals to within two inches of the anal fin. This specimen was a male, with two *holders*, each one foot two inches long, by one and a half in diameter. As this species is rare, we shall give its dimensions.

	Feet.	Inches.
Extreme length along curvature of back	7	8
Girth where thickest	4	8
Upper lip from muzzle	0	5
Mouth along curvature of upper lip	1	1
Eye round, in diameter	0	1·7
First dorsal, placed a little behind pectoral	1	1
Second dorsal, very small, over anal	0	2
Anal fin	0	2·5
Pectorals along their curved edge	1	6
Tail lunated, extent across tips	3	0
Upper lobe of ditto	1	9
Lower ditto of ditto	1	3
Distance between ventral and anal	0	10

Both this and the last species have, just above the tail, lateral projections, that in the centre rise into a blunt edge one inch from the general surface in the middle, and decline gradually into the general surface at both ends. These are about eight or nine inches long.

With Air-Holes and Anal Fin.

Galeus, or Tope. These chiefly differ from the true *Squali* in having the temporal apertures. One species is found on our coasts, and is not uncommon in the Firth of Clyde. It seldom exceeds, with us, five or six feet; and there is reason to suspect that the accounts sometimes given of its enormous size arise from confounding it with other sharks. Its skin has a very rank, offensive smell; its colour above is light cinereous, below white; nose long, flattened, and sharp at the point. The muzzle seems translucent toward the end; the nostrils are near the mouth; the first dorsal is placed towards the middle of the back, and is rather large; the second is near the tail; the tail is finned beneath, and ends in a sharp angle above.

Mustelus, Hound. This subdivision combines the characters of *Carcharias* and *Galeus*, but it has the temporal apertures and small rounded teeth. The species are of moderate size: Cuvier thinks that Linnæus has confounded two distinct species in his *Sq. mustelus.*

Notidanus, Dry-back. This subdivision is distinguished from *Galeus*, to which it has much resemblance, by the want of the first dorsal fin.

Sq. cinereus has a pointed muzzle, seven large branchial apertures, with a smooth skin compared to most of the family of sharks: the teeth are compressed and sharp; the dorsal is in the middle of the back. Length about three feet.

Sq. griseus. Colour, ash colour above, white below; six wide branchial apertures; teeth large, triangular above, serrated below; snout depressed and rounded; anal fin half way between the ventral and the tail. These two are natives of the Mediterranean. Another species of this subdivision is found in the Indian seas.

Selache, Basking Shark. Contains as yet only a single species, which unites to the general form of *Carcharias*, and to the air-holes of Galeus, large branchial apertures almost surrounding the neck. It is the gills of this species that have been erroneously described as a sort of whalebone. The mouth is provided with small teeth; the muzzle projects far beyond it. Nothing has ever been found in its stomach except the remains of Fuci or Algæ, in the numerous instances in which it has been captured in various parts of Scotland. They grow to thirty or thirty-six feet or more, and are fishes of great strength, but are harmless, indolent, and not very sensible to slight wounds. They often lie on the surface of the water, with their large dorsal fin exposed, and permit the approach of boats until the harpoon can be securely fixed in their bodies. They sometimes appear in shoals, but more commonly in pairs; and enter the bays on the western and northern shores of Britain in the months of June and July, but retire from the land on the approach of cold weather. The liver of a full-grown fish has been known to afford eight barrels of fine oil; and on this account the basking shark is considered as a profitable capture.

This is the species to which Sir E. Home erroneously referred the supposed sea-snake, driven on shore in Orkney in 1808; but the enormous length of that animal, the smallness of the vertebræ of the neck, and of its whole head, still preserved in the Museum of the University of Edinburgh, prove that idea to be inconsistent with the fact, and show that singular animal to have been some great species of cartilaginous fish as yet unknown to naturalists,—a species in which we are to look for the prototype of the famous sea-serpent of the Northern Skalds, and the wild legends of the Sagas.

Cestracion, Cuv. This sub-genus has the temporal apertures, the anal fin, and rounded teeth of *S. mustelus;* but the mouth is terminal, or at the extremity of the pointed muzzle; the middle teeth are small and pointed, those at the angles of the jaw are very broad, and rhomboidal. The only known species is a native of the Australian seas, the *Sq. Philippi*, which has an elongated lobe on each side of the head.

Species without Anal Fin, but with Air-Holes.

Spinax, Cuv.; Dog-fish. The *Sq. acanthias*, one of our most common sharks, is the type of this sub-genus. It has all the usual general characters of the *Squali*, but is without an anal fin; it possesses the temporal apertures, and is distinguished by a strong spine placed just before each dorsal. The muzzle of our *piked dog-fish* is long; the teeth in two rows, small, and cutting, bending from about the middle of the jaw toward the corners of the mouth. The tail is unequal; the upper lobe much the longest, but the lower lobe is *finned* for a considerable space beneath. The colour is of an ash-gray, dashed with brown above and white below: when young, the sides are mottled with whitish spots.

Several foreign species, especially those described by Rafinesque, appear mere varieties of our *Squalus spinax;* indeed this author has multiplied species on very slender authority.

Centrina, Cuv. So called from their strong dorsal spines. This subdivision has all the characters of *Spinax*, as far as the spines, want of the anal fin, and possession of temporal apertures; but the body is less elongated, the last dorsal is placed over the ventral, and the tail is short. The best known is the

Sq. centrina, Linn. A species uncommon in our seas, but occurring on various coasts of Europe. (Plate CCCVII. fig. 6.) The mouth is far beneath the snout; the nose is blunt; the head small; in the upper jaw are three rows of teeth, and one only in the lower, all of which are slender and pointed. The dorsal fins are large; the spine in the anterior pointing forward, that in the posterior is directed backwards; both project through the epidermis of the fins.

The *Squalus squamosus* belongs to this division. It is

Chondropterygii. Selachii.

allied to *Sq. centrina*, but has conspicuous, ovate, hard, carinated scales.

The skin, like that of most other sharks, is rough, with numerous sharp granular eminences.

Scymnus, Cuv. This subdivision has all the characteristics of *Centrina*, except the dorsal spines.

The European species is the *Sq. Americanus* of Broussonet and Shaw. It occurs on the coasts of France, off Cape Breton, which has been mistaken for the transatlantic Cape Breton. It appears to be identical with Risso's *Sq. Nicensis.*

The formidable animal described by O. Fabricius, in his *Fauna Groenlandica*, as *Sq. carcharias*, is now, from the descriptions of Scoresby and others, to be referred to this sub-genus. It is Scoresby's *Sq. borealis.* It wants the anal fin, but has the temporal orifices. It grows to the length of twelve or fourteen feet, and is six or eight in circumference. Scoresby mentions the singular appendages which he invariably found attached to the cornea of this animal. Some have supposed them to be parasitic animals. If so, it is singular that they should be so uniformly in the same position, and of the same size, about one or two inches long, and cleft at their fore extremity into two parts. This shark is peculiarly attracted by a dead whale, out of which it scoops at once masses of blubber as large as a man's head. The sailors believe this species to be blind, from its returning to feed on its favourite morsel, even after having a flensing knife run through its body; but this only shows its fondness for whale blubber,—to which circumstance we may also attribute the comparative safety of Greenland sailors who have fallen into the water when flensing the whale. But, if we may credit Fabricius, when this delectable food is not present, he will attack the slender bark of the Greenlanders.

To this division belong also the *Sq. spinosus* and *Labordii.*

Genus Zygæna, Cuv. This genus, which has the general form of body and fins of *Carcharias*, is distinguished by the extraordinary form of its head, that has no analogy in nature, except in some of the insect tribe. It is flattened horizontally, truncated in front, and extended laterally into two arms, at the extremity of which are the eyes, giving to the animal the form of a hammer. The mouth is below the centre of this singular head, and the nostrils at its anterior edges on each side. The most common in Europe is the *Sq. zygæna*, or hammer-headed shark, which often attains the length of sixteen or seventeen feet, and is formidable on account of its voracity and strength. It is found also around the West Indies, and in the Indian Ocean, especially at Taheite, where the natives are said, from their dexterity in swimming, to hold it in little dread. It is a very prolific animal. Two kindred species are known: the *Sq. Blochii*, Cuv., which differs in having the nostrils nearer the middle of the head, and its two dorsals much nearer the tail; and *Sq. tiburo*, or heart-headed shark, a much rarer species, which we have received from the coast of Guyana. We here figure *Zygæna Lewinii*, a species captured off the south coast of New Holland. Plate CCCVII. fig. 5.

Genus Squatina, Dumer.; Angel-fish. Has the temporal apertures without the anal fin; but its mouth is terminal, and its eyes are both placed on its dorsal surface, in which it differs from all the sharks. The head and body are flattened; the pectoral fins are extremely broad, and project forward to the sides of the head, but are separated from it and the neck by a fissure, in which the branchial apertures are placed; the two dorsals are behind the ventrals, and the tail is equally finned above and below the spinal column.

The best-known species is the *Sq. squatina*, Linn., or angel-shark, which grows to eight or ten feet. It is a bold and voracious fish; when captured, it bites with great fury; it preys much on flat fish; it has tentacula on its upper lip; its eyes, placed obliquely, give it a sinister look. The English name has been given ironically to this hideous creature, which is by seamen generally termed *devil-fish.*

The teeth are slender, sharp, and dilated at their base; the dorsal fins very small, the pectorals very broad, the ventral large, and enclosing the male organs. The upper lobe of the tail longer than the lower. It is very prolific, fourteen young being sometimes found in its belly; twelve frequently.

To this genus we must also refer the *Sq. aculeatus* of the Mediterranean.

Genus Pristis, Lath.; Saw-fish. This last genus has the general form of the *Squali*, but is more flattened in front, and has the branchial apertures beneath, like the *Rays.* The most peculiar character, however, consists in the great depression and extension of the snout, which has on each side a row of strong teeth or spines, which are trenchant on the fore-side, and mucronated. These spines are not, however, their true teeth. These are lodged in the mouth, and are very small and rounded. But, with their formidable beak, they are said successfully to attack the larger Cetacea. In the fœtal Pristis the rudiments of these osseous spines are mere tubercles, and the snout is folded up over the head of the embryon. These spines are not, like the teeth of cartilaginous fishes, attached by ligaments to the bones, but are firmly implanted in the bone of the snout.

The best-known species is the *Sq. pristis* of Linn. or *Pristis antiquorum.* It grows to a great size. We have measured snouts more than ten inches in diameter, and four feet seven inches in length, with sixteen or eighteen spines on each side, some of which projected three inches. The animal attains the length of sixteen or eighteen feet. There are other species chiefly distinguished by the number and form of these spines: as *Pristis cuspidatus,—Pr. pectinatus*, with numerous slender teeth,—*Pr. microdon,* —*P. cirratus*, with alternate long and short teeth,—and *Pr. semi-sagittatus*, a small Indian species, in which the spines are deeply denticulated on the posterior edge.

Genus Raia (or Ray) of Linnæus. This great genus of the Selachii is very numerous, and the species often grow to a vast size. They are readily recognised by their flattened body, like the *Pleuronectes*, forming a horizontal disk, very broad in proportion to its thickness, in consequence of the body graduating into the enormous pectorals of the animal, which unite in front with the snout, and extend on both sides of the abdomen to the base of the ventral fins. See skeleton of the thorn-back (*R. clavata*), Plate CCCVII. fig. 9. The scapula of these vast pectorals are articulated with the spine just behind the branchial apertures. These apertures, the nostrils, and mouth, are on the ventral surface of the fish; the temporal orifices, and the eyes, are on the dorsal surface. The dorsal fins are usually placed on the tail. These animals are oviparous. Their eggs are coriaceous, square, with long angles. The subdivisions of Cuvier are the following.

Genus Rhinobatus, Sch. Distinguished by the length of the snout; connects the sharks and rays. They have a thick and fleshy tail, like *Squali*, with two dorsal and two caudal fins. Their snout and pectorals form a sharp rhomboid. Their teeth are placed in a quincunx arrangement. In some the first dorsal is placed over the ventral fins, in others it is placed farther back. The best known is the Mediterranean *Raia rhinobatus*, which is found four feet in length. The others are, *R. Thouiniana* (Plate CCCVII. fig. 7), supposed by Cuvier a variety of that just named, but it has such difference of form as to entitle it to be considered a distinct species; *R. djiddensis*, Forsk.; one described by Russel, *R. suttivara;* and one from Brazil, *R. electricus*, Marc, which, as its specific name implies, has been said to possess some of the properties of the *Torpedo.*

Genus Rhina, Sch. This subdivision has a short, rounded muzzle; in other respects it is like the last named. The species is *R. ancylostomus* of Bloch.

Genus Torpedo, Dum. This subdivision is short, and rather fleshy. The body appears a nearly circular disk, the anterior edge being composed of two projections of the muzzle, which stretch sidewise, and unite with the pectorals. The space between these last and the head is entirely filled with the very extraordinary electric apparatus first accurately described by John Hunter. It consists of irregular columns, varying from one and a half inch to one fourth of an inch in length by 0·2 broad. They are irregular hexagons or pentagons, reaching from surface to surface of the fish, and forming (in that dissected by Hunter) an electric organ five inches long, varying in breadth from three to about one and a half inches. Their number on both sides is about 940 in a small fish; but in a large one there were 2364. Their coats are thin and transparent; they are horizontally divided by thin partitions, so numerous that one inch of these columns contained 150 dissepiments filled with fluid. This curious apparatus is supplied with numerous nerves from the eighth pair. The columns are firmly united by cellular substance. When the skin covering this apparatus is touched, the person receives a violent shock at each contact; and it is probable that in this way the species stuns its prey. The animal can give the shock at pleasure; but if often reiterated, the shocks are weakened, until the nervous energy of the fish is recruited by rest. This animal electricity is conducted and intercepted by the same substances that conduct and intercept ordinary artificial electricity. We here figure *T. Bancroftii.* Plate CCCVII. fig. 8.

Several species occur in Europe, which Linnæus confounded together under the title of *Raia torpedo.* We have *Torpedo naske*, distinguished by having no fleshy dentations at the edges of its temporal apertures; its dorsal spots vary from one to five: *Torp. Galvanii* has seven dentations round its air-holes, and is of an uniform brown, sometimes marbled or spotted with darker tints: *Torp. marmorata* is another Mediterranean species, described by Risso. We know several foreign species, such as *Torp. temeree* and *Torp. nalatemeree* of Russel, *Torp. timlei?* of Bloch.

Genus Raia, *properly so called.* Has a rhomboidal body united to a slender tail, which has near its extremity two small dorsals, with, in some instances, a vestige of a caudal fin. The teeth are small, and disposed in a quincunx arrangement on the jaws. Several species inhabit the European seas, some of which are yet indifferently distinguished by naturalists. As articles of diet, some of them are frequently used; and though seldom seen at the tables of the rich, they are by no means despicable food, especially their pectorals.

Raia clavata, or thornback, is a common species, distinguished by the roughness of its back, and the strong osseous oval plates, each furnished with a curved prickle, that are irregularly scattered on both its surfaces. These plates are variable in number, and therefore do not afford any diagnostic character.

Raia rubus, rough ray. There is much confusion among Ichthyologists respecting this and the next species. Cuvier seems to think that the *Batis* of Pennant and *Rubus* of Lacépède are the same; but *Rubus* of Pennant and Willughby is certainly different from the skate, and distinguished from the last by its less pointed nose and the greater length of the tail, and is more thickly studded with small spines, not only on the back, but on the fins and belly, which are equally rough with the back. There are three rows of large spines down the tail, the surface of which is irregularly beset with small prickles. It is to this species that we confine the name of *R. rubus.* It is less common than *R. batis*, and is a much smaller fish. Found among the Hebrides.

R. batis, the skate. One of the thinnest and broadest of the tribe; but sometimes growing to an immense size, and weighing 200 pounds. The nose, though not very long, is pointed. Sometimes the surface of the back is marbled with dusky and white. Along the tail is one row of spines; a few are irregularly dispersed on the sides of the tail, and the fins of the males have many small spines.

The spring is their season of love; and when coupling, both may be drawn into the boat, though one only has taken the bait. The male *holders* appear to be true organs of penetration, as we have been assured by fishermen. The eggs have the form of coriaceous parallelograms, and are vulgarly with us termed *purses*, which the females begin to cast in May, and continue to perfect and cast till September. This species is often eaten, as well as the thornback, both in the greatest perfection in spring.

R. oxyrinchus, the sharp-nosed ray. We do not agree with Cuvier in confounding this with *R. batis.* The form of the nose is much longer and narrower; the body much smoother than any species we have mentioned, though there are triple rows of small spines along the tail. A single row of small spines runs down its back, and a few are scattered about the eyes. The teeth too, in this species, differ from those of the skate, being bent inward, and less granular. It is not inferior in size to the skate. Indeed specimens are said to have been seen of the weight of 500 pounds.

Some species of this division have a sort of membranous expansion, like a fin elevated in the middle of the back. This has been seen also in rays in other respects resembling the skate; but it is particularly conspicuous in *R. Cuvieri.* To this division likewise belong *R. undulata*, Lacép., *R. fullonica*, *R. marginata*, *R. miraletus*, Rondelet, *R. picta*, *R. alba*, and others.

Genus Trygon, Adans. Is characterised by having the tail armed with a spine, finely serrated on both sides; and by the teeth, which are slender, and crowded in a quincunx. Form of the disk obtuse; some have the tail fleshy, but in many it is very slender, and almost destitute of the rudiment of a fin. Most of them have smooth bodies; their caudal spine long—a powerful weapon of offence and of defence, which inflicts severe and dangerous wounds.

R. pastinacea, Linn.; sting ray. Is found on the European coasts. Some have a few prickles on the back; it is tuberculated in others. In some species the lower part of the tail has a broad membrane,—others have a short tail terminated by a fin. The principal species are, *P. tuberculata; P. Wolga Tenkée*, Russ.; *P. sephen*, Forsk.; *P. Gesneri*, Cuv.; *P. lymna*, *P. Jamaicensis*, Cuv.; *P. cruciata*, Lacép.; *P. kunsua*, Russ.

Genus Anacanthus, Ehrenb. Has a general resemblance to *Pastinaca*, but is destitute of the spine and anal fin. This sub-genus is formed from the description received of the large *shagreen ray* of the Red Sea, in which the grains are stellular.

R. orbicularis, Bl. belongs to this division.

Genus Myliobatis, Dumer. This sub-genus has the head projecting beyond the pectorals altogether; and these fins have a greater proportional breadth than in the other rays, which gives these animals no small resemblance to a bird with its wings extended; but their name is derived from the millstone-like form of their broad flat teeth, planted on their jaws like the stones of a pavement: their tail, long, slender, and tapering to a point, is armed, as in *Pastinaca*, with a strong spine, toothed on both sides, and is furnished, just above the spine, with a small dorsal fin. In some instances there are two or more such spines.

Raia aquila, or eagle ray, grows to an immense size: it has a projecting parabolic snout: the plates or teeth in the middle of the jaws are in a single row, much broader than long; but the lateral ones are hexagons in three ranges. The eyes are prominent, the tail very long and slender. It has been known to measure fifteen feet in length, and to weigh 300 lbs. It is said to swim with a slow sailing motion, and when captured vibrates its tail with great activity. It yields much fine oil. Inhabits the Mediterranean, the Atlantic, and Indian Oceans. To this division also we must refer the following species:

R. guttata, Shaw, Plate CCCVII. fig. 10, synonymous with the *Eel-Tenkee* of Russel; *R. fasciata*, Shaw; *Myl. bovina*, and *Myl. marginata*, Geoff.; which last has the snout cleft into two short lobes, and belongs to the sub-genus *Rhinoptera* of Kuhl.

Genus Cephaloptera, Dum. The last division of the rays is distinguished by the bifurcation of the appendages to the head, derived from the pectorals, which give the species the appearance of being horned. The head is truncated between these projections; the teeth are less strong than those of *Pastinaca*, and are finely crenulated on the edges; the tail, spine, and small dorsal fin, resemble those of *Myliobatis*.

The best known is the gigantic *Chephal. giorna* of the Mediterranean, the back of which is blackish, bordered with violet. (Plate CCCVII. fig. 11.) The animals which are mentioned by Shaw as *Raia manatia*, *R. fabroniana*, and *R. Banksiana*, are considered by Cuvier as doubtful species.[1] It is probable that the *R. diabolus* of Willughby, described by Duhamel, and said also to occur at the Azores, may be a distinct species, or perhaps the same as the *Eregoodoo-Tenkée* of Russel, which Cuvier is disposed to consider as a species well established. *Ch. massena* of Risso is a Mediterranean species, twelve feet long and twenty-seven in circumference. The female weighs 1250 lbs., the male about 800 lbs. Top of the horns black, the base bluish externally, and white on their inner sides. Of the pair described by Risso, the female was first taken; and the author adds, that the male continued constantly about the boat for three days, as if bewailing the fate of his companion, and was then found floating dead.

FAMILY II.—CYCLOSTOMI, OR SUCKERS.

The suckers, as far as their skeleton is concerned, are the most imperfect of all vertebrate animals. The bodies of all their vertebræ are traversed by a single tendinous cord, uniformly tapering from head to tail, which almost reduces the vertebræ to cartilaginous rings, scarcely distinct from one another, and not even cartilaginous through their whole circumference. The body is terminated abruptly in front by a fleshy circular or semicircular mouth, supported on a cartilaginous ring formed by the union of the palatal and maxillary bones. No ribs are distinguishable: there are no solid branchial arches; but the small branchial rays, scarcely recognisable in *Squalus* and *Raia*, are in them fully developed, and united together into a sort of lattice. The gills, instead of the pectinated form they have in almost all other fishes, exhibit the appearance of little sacs, from the union of each gill with that adjacent. The labyrinth is enclosed in the cranium, the nostrils have only a single aperture, in front of which is a cul-de-sac, mistaken by some authors for a temporal orifice. The intestine is straight and narrow, with a spiral valve.

Genus Petromyzon, Linn. This genus is distinguished by seven branchial apertures on each side; the skin above and below the tail is elevated in a rayless fin. The sub-genera are the following:

Genus Petromyzon, Dum. or Lamprey *properly so called.* Maxillary ring armed with strong teeth, within which are tubercles, with a hard enamel lining the lips. This ring is suspended by a piece answering to an inter-maxillary bone. The tongue is furnished with two longitudinal ranges of small teeth, and is capable of vigorous motion. The tongue acting like a piston in the circular mouth, is an essential part of the mechanism by which the fish is enabled to attach itself firmly to stones, or to fasten itself to the larger fishes, which it is thus enabled to suck and devour at its leisure. In respiration, the water is carried from the mouth to the gills by a canal under the gullet, and pierced with lateral apertures. The dorsal fin is farther forward than the anus, and a second unites with the tail. The European species are,

P. marinus, the greater lamprey, which grows to the length of more than three feet. (Plate CCCVII. fig. 12.) It is considered as a delicate food, and is caught as it ascends rivers in the end of winter and spring.[2] Colour yellowish, marbled with brown. First dorsal fin very distinct from the second. This fish is common in the Severn, and in the mouths of many European rivers. Its supposed *hermaphroditism* is mentioned by Sir Everard Home.[3]

P. fluviatilis, the lampern, or nine-eyed eel.[4] Length from twelve to eighteen inches; olive back, silvery below; first dorsal distinct from the second. Two thick teeth, separate, in the top of the maxillary ring. Ascends rivers from the sea; swarms in the Thames, Severn, and Dee. Vast quantities taken in England are sold to the Dutch for the turbot fishery. It abounds in the rivers on the southern side of

---

[1] There is no doubt, however, that one or other of those names refers to an existing though obscurely known species, of enormous size. A specimen of the *Banksian ray* is said to have been found on the coast of Barbadoes, of such a vast weight that seven yoke of oxen were required to draw it. A figure of the *Ceph. manatia* was sent to Lacépède, the original of which was alleged to be nearly twenty feet long. "It seems that it is to this species we may refer what Barrère and other travellers have said of the enormous rays of the American and equinoctial seas, which spring above the surface of the water, and splash it to an immense distance on falling into it. Levaillant, in his second voyage to Africa, speaks of having seen one, the smallest of three, which swam round about the vessel, about twenty-five feet long and more than thirty wide; and Sonnini speaks of one which appeared to him larger and wider than the ship in which he was sailing." "Colonel Hamilton Smith once witnessed the destruction of a soldier by one of these Cephalopteri, off Trinidad. It was supposed that the soldier, being a good swimmer, was attempting to desert from the ship, which lay at anchor in the entrance of the Bocca del Toro. The circumstance occurred soon after daylight; and the man, being alarmed by the call of a sailor in the main cross-trees, endeavoured to return to the vessel; but the monster threw one of his fins over him, and carried him down. The colonel is positive as to this fish being a Cephalopterus." (Griffith's *Animal Kingdom*, vol. x. p. 653.)

[2] The death of Henry I. was attributed to a too plentiful meal of lampreys. They seem, however, to have continued in high esteem in spite of that "untoward event;"—at least we find Henry IV. granting protection to such ships as brought over lampreys for his *royal consort's* table; and his successor issued a warrant to William of Nantes, for supplying himself and his army with these fishes, wherever they might happen to march. (*Rymer*, ix. 544, as quoted by Pennant.)

[3] *Phil. Trans.* 1815, 266.

[4] "Whether," says Sir Thomas Brown, "Lampries have nine eyes, as is received, we durst refer it unto Polyphemus himself, who had but one to judge it; an error concerning eyes, occasioned by the error of eyes, deduced from the appearance of divers cavities or holes on either side, which some call eyes that carelessly behold them; and is not only refutable by experience, but also repugnant unto reason." (*Pseudodoxia Epidemica.*)

Conclusion. the Baltic. Both these animals are very tenacious of life, and will live many days out of water.

P. planeri. About ten inches long; greatly resembles the preceding; but the two dorsal fins are united. It is also an European river fish.

The other species described by Shaw appear to be but mere varieties of the above.

Genus Myxine, Linn. This genus is properly separated from the lampreys, to which, however, it has much resemblance. It is distinguished by having only two spiracles, and by wanting eyes. The species best known, *Myxine glutinosa*, Linn., or glutinous hag, was classed by Linnæus with the Vermes; but its real place is among chondropterygian fishes. The mouth is a membranous ring, with a single tooth on its superior part; while the strong dentations of the tongue are arranged in two rows on each side, so as to give to these animals the appearance of having lateral jaws, like insects or nereides; but the rest of their structure corresponds with *Petromyzon*, and their tongue in particular performs the office of a piston in exhausting the mouth, so as to enable them to adhere to other bodies, like the lamprey. The lips are furnished with eight cirrhi, and above is an aperture communicating with the mouth; the body is nearly cylindrical, and terminates in a fin which surrounds the tail. The intestine is simple, wide, and straight, as viewed externally; but it is plaited within: the liver has two lobes: the eggs grow to a considerable size. When taken and confined in a large glass jar, a single fish will pour so much mucus from its lateral pores as to give the water the appearance of jelly.

Three species are known, which Cuvier makes the types of a corresponding number of sub-genera, as follows:

1*st*, Heptatremus, Dumer. With seven branchial apertures, as in the lamprey. This animal is the *M. Dombeyi*, found on the coast of South America by Dombey. It has a rounded head; the teeth are sharp, and arranged in two rows, respectively of fourteen and twenty-two, and with one longer than the rest in the upper part of the mouth; tail rounded at the extremity, and terminated by a very shallow fin.

2*d*, Gastrobranchus, Bloch. The intervals of the branchial rays open into a common canal for each side, and these two canals terminate in two apertures under the heart of the animal, about one third of its length from the head.

The only known species is the European *Myxine glutinosa*, Linn. On the Yorkshire coast the fishermen occasionally find that it has entered the mouths of fish on the hooks of the long lines, and devoured the flesh, leaving only the skin and bones. They often catch it in the fish thus emptied, and term it the *sea-hag*. It grows to the length of six or eight inches.

3*d*, Ammocætes, Dumer. Is destitute of a real skeleton; body cylindrical, with numerous annular lines around it, that give it much the appearance of a worm. It lives in the mud of rivers. Mouth cirrhated, toothless, lobated below, and incapable of adhering *by suction* to other bodies; fins very shallow; tail sharp at the tip; no tracheal tube, as in the rest, but the gills receive water from the œsophagus. The only species is *P. branchialis*, Shaw, the *Pride* of Pennant, which grows to six or eight inches long, and is as thick as a goose-quill. It inhabits the rivers of Oxfordshire, and occurs in various parts of the European continent.

We have now brought our exposition of the modern system of Ichthyology to a close. The subjects of which it treats are of deep and sustaining interest, in a philosophical point of view, and of the highest and most immediate importance when considered in relation to the economical advantages derivable by the human race. We have endeavoured to combine with the precise and technical expression of the generic and other characters such miscellaneous information as could be collected from authentic sources, with a view to render the subject more palatable to the general reader;—and if any great deficiency in that department is observable, we hope it may in some measure be attributed to the nature of this branch of natural history, the objects of which inhabiting another element from ourselves, have thus their on-goings too often veiled from mortal sight by a "world of waters,"—which no eye can pierce but the eye of Him who called the light out of darkness, and who created the "heavens and the earth, the sea, and all that in them is."

We shall conclude with a brief allusion to a subject of the highest interest to the naturalist,—one to which we believe no reference has been made in the introductory portion of the present treatise, and which, we regret, our now exhausted space must prevent us from exhibiting at greater length,—we mean the *geographical distribution* of fishes. Our knowledge of the laws which regulate that distribution is meagre in the extreme; in other words, the facts concerning their true localities are few, and have never been properly generalised. From the immeasurable extent and continuous nature of the fluid which they inhabit, they are supplied by nature with greater facilities of dispersion than most other animals; and the greater equality of the temperature of water, compared with that of earth or air, admits in several instances of the same species inhabiting almost every latitude from pole to pole. Those races especially, which, travelling together in vast shoals, speedily consume the natural food which each particular spot affords, are obliged, like the pastoral tribes of old, or the woodland hunters of America, to remove from place to place in search of additional supplies; and thus the species acquires a more widely extended distribution. It is thus that the cod and herring are spread over the whole extent of the Northern Ocean, and in undiminished numbers, notwithstanding the war of extermination which man and other voracious animals appear to wage against them. Those species which lead a solitary, and, as it may be called, a stationary life, are frequently confined within very narrow limits. The Chætodons, for example, which delight in rocky coasts covered with madrepores, attach themselves to the torrid zone, which produces so abundantly those magnificent ornaments of the sea. But though thus confined to particular spots, from which the individuals of the species seldom wander, the species itself may be said to be repeated again in different regions, separated from each other by almost insurmountable obstacles. Thus many of what may be termed stationary species are found identically the same along the coasts of Brazil, in the Arabian Gulf, and over the multiplied shores of Polynesia. It has hence been concluded, that such species, incapable of colonizing themselves by leaving their accustomed shores, and hazarding a journey across unknown oceans, have either been created in more places than one, or have been enabled to transport themselves by means different from any of those that are now available in the ordinary course of nature.

If the natural means by which the more powerful species inhabiting the saline waters of the ocean have spread themselves from clime to clime, be to a certain extent within the reach of our comprehension, it is otherwise with those peculiar to rivers, and the waters of inland lakes. How these have contrived to migrate from one region to another, and to people with identical species the depth of far-removed and solitary waters, separated from each other by chains of lofty mountains, or wide extended wastes of desert sand, is a problem which, in the present state of our knowledge, we seek in vain to solve. It may indeed at times happen that spawn or ova are carried by water-fowl

Index.

from one great central reservoir to another, and thus the rivers of half a continent may be put in possession of species unknown before;—but this supposition scarcely suffices to account for the general diffusion of certain species, and still less for the narrow restriction of others equally exposed to the chances of that aërial flight.[1] (T.[2])

INDEX.

[1] Consult M. Gaimard's *Mémoire sur la Distribution Geographique des Poissons;* an Essay on Geography considered in relation to natural history, in the seventh volume of the *Diction. Classique d'Hist. Nat.;* and our *Illustrations of Zoology*, letter-press preceding plate xx.

[2] The author of the preceding treatise has to acknowledge his obligations to Sir William Jardine, Bart., for the use of his notes on the Salmonidæ,—to Professor Traill, for assistance in relation to the Apodal Malacopterygian, and Chondropterygian tribes,—and to Dr Allan Thomson, for his aid in drawing up the history of the Clupidæ, and of the Sub-brachian Malacopterygians.

ICHTHYOPHAGI, FISH-EATERS, a name given to those who lived wholly on fishes. The word is Greek, being compounded of ἰχθυς, *piscis*, fish, and φαγειν, *edere*, to eat. This name or term has been applied to different people.

The Ichthyophagi spoken of by Ptolemy are placed by Sanson in the provinces of Nanking and Xantong. Agatharcides calls all the inhabitants between Carmania and Gedrosia by the name of *Ichthyophagi*. From the accounts given us of the Ichthyophagi by Herodotus, Strabo, Solinus, Plutarch, and others, it appears indeed that they had cattle, but that they made no use of them, excepting to feed fish withal.

ICHTHYPERIA, a term in *Natural History*, applied to the bony palates and mouths of fishes, usually met with either fossil, in single pieces, or in fragments. They are of the same substance with the bufonitæ; and are of various figures, some being broad and short, others longer and slender, some gibbose, and others plainly arched. They are likewise of various sizes, from the tenth of an inch to two inches in length, and an inch in breadth.

ICKENILD STREET is that old Roman highway, so denominated from the Icenians, which extended from Yarmouth in Norfolk, the eastern part of the kingdom of the Iceni, to Barley in Hertfordshire, giving name in the way to several villages, as Ickworth, Icklingham, and Ickleton, in that kingdom. From Barley to Royston it divides the counties of Cambridge and Hertford; from Ickleford it runs by Tring, crosses Bucks and Oxfordshire, passes the Thames at Goring, and extends to the west part of England.

ICOLMKIL. See IONA.

ICONIUM, at present COGNI, formerly the capital of Lycaonia in Asia Minor. St Paul, proceeding to Iconium (Acts, xiii. 51, xiv. 1), in the year of Christ 45, there converted many Jews and Gentiles. It is believed, that in his first journey to this city he converted St Thecla, so celebrated in the writings of the ancient fathers. But some incredulous Jews excited the Gentiles to rise against Paul and Barnabas, and as the former were upon the point of offering violence to them, the apostles were obliged to fly for security to the neighbouring cities. St Paul undertook a second journey to Iconium in the year 51, but we know no particulars concerning his journey which relate especially to Iconium.

ICONOCLASTES, or ICONOCLASTÆ, breakers of images; a name given to all those who reject the use of images in religious matters. The word is Greek, formed from εικων, *imago*, image, and κλαστειν, *rumpere*, to break.

In this sense, not only the reformed, but some of the eastern churches, are called Iconoclastes, and esteemed heretics, as opposing the use of images in the worship of God and the saints, and breaking their figures and representations in churches.

The opposition to images began in Greece under the reign of Bardanes, who was created emperor of the Greeks soon after the commencement of the eighth century, when the worship of images became common. But the tumults thus occasioned were quelled by a revolution, which, in 713, deprived Bardanes of the imperial throne. The dispute, however, broke out with redoubled fury under Leo the Isaurian, in the year 726, who issued an edict abrogating, as some say, the worship of images, and ordering all images, except that of Christ's crucifixion, to be removed from the churches; but, according to others, this edict only prohibited the paying to them any kind of adoration. This edict occasioned a civil war, which ravaged part of Asia, and afterwards reached Italy. The civil commotions and insurrections in Italy were chiefly promoted by the Roman pontiffs, Gregory I. and II. Leo was excommunicated, and his subjects in the Italian provinces rising in arms, either massacred or banished all the emperor's deputies and officers. In consequence of these proceedings, Leo assembled at Constantinople in 730 a council, which degraded Germanus, the bishop of that city, who was a patron of images; he also ordered all the images to be publicly burned, and inflicted a variety of severe punishments upon such as were attached to idolatrous worship. Hence arose two factions; one of which adopted the adoration of images, and on that account were called *iconoduli* or *iconolatræ;* whilst the other maintained that such worship was unlawful, and that nothing was more worthy the zeal of Christians than to demolish and destroy those statues and pictures which were the occasions of this gross idolatry; and hence they were distinguished by the titles of *iconomachi* (from εικων, *image*, and μαχω, *I contend*) and *iconoclastæ*. The zeal of Gregory II. was not only imitated, but even surpassed, by his successor Gregory III. in consequence of which the Italian provinces were separated from the Grecian empire.

Constantine, surnamed *Copronymus* (from κοπρος, *stercus*, and ονομα, *name*, because he was said to have defiled the sacred font at his baptism), succeeded his father Leo in 741, and in 754 he convened a council at Constantinople, regarded by the Greeks as the seventh œcumenical council, which solemnly condemned the use of images in public worship. Leo IV. who was declared emperor in 775, pursued the same measures, and had recourse to the coercive influence of penal laws, in order to extirpate idolatry. Irene, the wife of Leo, poisoned her husband in 780; assumed the reins of empire during the minority of her son Constantine; and in 786 summoned a council at Nice in Bithynia, known by the name of the Second Nicene Council, which abrogated the laws and decrees against the new idolatry, restored the use of images and of the cross, and denounced severe punishments against those who maintained that God was the only object of religious adoration. In this contest, the Britons, Germans, and Gauls, were of opinion that images might be lawfully continued in churches, but they considered the worship of these as highly injurious and offensive to the Supreme Being. Charlemagne distinguished himself as a mediator in this controversy. He ordered four books concerning images to be composed, refuting the reasons urged by the Nicene bishops to justify the use of images; and these books he sent to Adrian the Roman pontiff in 790, in order to engage him to withdraw his approbation of the decrees of the last council of Nice. Adrian wrote an answer; and in 794, a council of three hundred bishops, assembled by Charlemagne at Francfort-on-the-Mayn, confirmed the opinion contained in the four books, and solemnly condemned the use of images. In the Greek church, after the banishment of Irene, the controversy about images broke out anew, and was carried on by the contending parties, with various and uncertain success, during the half of the ninth century. But the scene changed on the accession to the empire of Leo the Armenian, who in 814 assembled a council at Constantinople, which abolished the decrees of the Nicene council. His successor Michael, surnamed *Balbus*, disapproved of the worship of images, and his son Theophilus treated them with great severity; but the Empress Theodora, after his death, and during the minority of her son, assembled a council at Constantinople in 842, which reinstated the decrees of the second Nicene council. The council held at the same place under Photius, in 879, and reckoned by the Greeks the eighth general council, confirmed and renewed the Nicene decrees.

The Latins were generally of opinion, that images might be suffered as the means of aiding the memory of the faithful, and of calling to their remembrance the pious exploits and virtuous actions of the persons whom they represented; but they detested all thoughts of paying them the least marks of religious homage or adoration. The council assembled at Paris in 824, by Louis the Meek, resolved to allow the use of images in the churches, but severely prohibited rendering them religious homage. Nevertheless, towards the conclusion of this century, the Gallican clergy began to pay a kind of religious homage to the images of saints, and their example was followed by the Germans and other nations. However, the Iconoclastes still had their adherents amongst the Latins. The most eminent of these was Claudius, bishop of Turin, who, in 823, ordered all images, and even the cross, to be cast out of the churches, and committed to the flames; and he wrote a treatise, in which he declared against the use as well as against the worship of images. He condemned relics, pilgrimages to the Holy Land, and all voyages to the tombs of saints; and to his writings and labours it was owing that the city of Turin and the adjacent country was, for a long time after his death, much less infected with superstition than the other parts of Europe. The controversy concerning the sanctity of images was again revived by Leo, bishop of Chalcedon, in the eleventh century, on occasion of the Emperor Alexius converting the figures of silver which adorned the portals of the churches into money in order to supply the exigencies of the state. The bishop maintained that he had been guilty of sacrilege, and published a treatise in defence of his views. The emperor assembled at Constantinople a council, which determined that the images of Christ and of the saints were to be honoured only with a relative worship; and that invocation and worship were to be addressed to the saints only as the servants of Christ, and on account of their relation to him as their master. Leo, being dissatisfied with these decisions, was sent into banishment. In the western church, the worship of images was disapproved and opposed by several considerable parties, as the Petrobossians, Albigenses, Waldenses, and others, until at length this practice was entirely abolished in many parts of the Christian world by the Reformation.

ICONOGRAPHIA (derived from εικων, *image*, and γραφω, *I describe*), the description of images or ancient statues of marble and copper, also of busts and semi-busts, penates, paintings in fresco, mosaic works, and ancient pieces of miniature.

ICONOLATRÆ, or ICONOLATERS, or ICONODULI. See ICONOCLASTES.

ICOSAHEDRON, in *Geometry*, a regular solid, consisting of twenty triangular pyramids, the vertices of which meet in the centre of a sphere supposed to circumscribe it, and therefore have their height and bases equal; wherefore the solidity of one of these pyramids multiplied by twenty, the number of bases, gives the solid contents of the icosahedron.

ICOSANDRIA (from εικοσι, *twenty*, and ανηρ, *a man* or *husband*), the name of the twelfth class in Linnæus's sexual method, consisting of plants with hermaphrodite flowers, which are furnished with twenty or more stamina, that are inserted into the inner side of the calyx or petals. See BOTANY.

ICTINUS, a celebrated Greek architect, who lived about 430 B. C., built several magnificent temples, and amongst others that of Minerva at Athens.

IDA, in *Ancient Geography*, a mountain situated in the heart of Crete, being the highest in the island, round, and in compass about sixty stadia (Strabo); the nursing place of Jupiter, and where his tomb was visited in Varro's time. There was another *Ida*, a mountain of Mysia, or rather a chain of mountains, extending from Zeleia, on the south of the territory of Cyzicus, to Lectum, the utmost promontory of Troas. The abundance of its waters became the source of many rivers, and particularly of the Simois, Scamander, Æsopus, and Granicus. It was covered with green wood, and the elevation of its top opened an extensive view of the Hellespont, and the adjacent countries; for which reason it was, according to Homer, frequented by the gods during the Trojan war. The top was called *Gargara*, and celebrated by the poets for the judgment of Paris on the beauty of the three goddesses, Minerva, Juno, and Venus.

IDALIUM, in *Ancient Geography*, a promontory on the eastern side of Cyprus; now Capo di Griego. It was sacred to Venus, and hence the epithet *Idalia* given her by the poets.

IDEA, defined by some to be the reflex perception of objects, after the original impression has been made on the mind. In common language, it is used as synonymous with *notion* or *conception*.

IDENTITY denotes that by which a thing is itself, and not any thing else; in which sense *identity* differs from *similitude* as well as *diversity*.

IDES, in the ancient Roman calendar, were eight days in each month, the first of which fell on the 15th of March, May, July, and October; and the 13th day of the other months of the year. The origin of the word is contested. Some suppose it to have been formed from ἰδειν, *to see*, because the full moon was commonly seen on the days of the ides; others derive it from ειδος, *species*, *figure*, on account of the image of the full moon then visible; others from *idulium* or *ovis idulis*, a name given by the Etruscans to a victim offered on that day to Jupiter; and others again from the Etruscan word *iduo*, meaning to *divide*, because the ides divided the month into two nearly equal parts.

The ides came between the *kalends* and the *nones*, and were reckoned backwards. Thus they called the 14th day of March, May, July, and October, and the 12th of the other months, the *pridie idus*, or the day before the ides; the next preceding day they called the *tertia idus;* and so on, reckoning always backwards till they came to the *nones*. This method of reckoning time is still retained in the chancery of Rome, and in the calendar of the Breviary.

The ides of May were consecrated to Mercury; and the ides of March were ever esteemed unfortunate, after Cæsar's murder on that day. The time after the ides of June was reckoned fortunate for those who entered into matrimony; the ides of August were consecrated to Diana, and were observed as a feast-day by the slaves. On the ides of September, auguries were taken for appointing the magistrates, who formerly entered into their offices on the ides of May, and afterwards on those of March.

IDIOCY, a defect of understanding. Both idiocy and lunacy excuse from the guilt of crimes. For the rule of law as to lunatics, which may also be easily adapted to idiots, is, that *furiosus furore solum punitur.*. In criminal cases, therefore, idiots and lunatics are not chargeable for their own acts, if committed when under these incapacities; not even for treason itself. Also, if a man in his sound memory commits a capital offence, and before arraignment becomes mad, he ought not to be arraigned for it; because he is not able to plead to the charge with that advice and caution that he ought. And if, after he has pleaded, the prisoner becomes mad, he shall not be tried; for how can he make his defence? If, after he be tried and found guilty, he loses his senses before judgment, judgment shall not be pronounced; and if, after judgment, he becomes of unsound memory, execution shall be stayed; for peradventure, says the humanity of the English law, had the prisoner been of sound memory, he might have alleged something in stay of judgment or execution. But if there be any doubt whether the party be *compos* or not, this shall be tried by a jury; and if he be found *non compos*, a total idiocy, or absolute insanity, excuses from the guilt, and of course from the punishment, of any criminal action committed under such deprivation of the senses; but if a lunatic has lucid intervals of understanding, he shall answer for what he does in those intervals, as if he had no deficiency. It was the doctrine of the ancient English law, that persons deprived of their reason might be confined till they recovered their senses, without waiting for the forms of a commission or other special authority from the crown; but now a method is chalked out for imprisoning and sending them to their proper homes.

The matrimonial contract, likewise, cannot take place in a state of idiocy. It was formerly adjudged, that the issue of an idiot was legitimate, and his marriage valid. But since consent is absolutely requisite to matrimony, and neither idiots nor lunatics are capable of consenting to any thing, therefore the civil law judged much more sensibly when it made such deprivations of reason a previous impediment, though not a cause of divorce if they happened after marriage. Modern resolutions have adhered to the sense of the civil law, by determining that the marriage of a lunatic, not being in a lucid interval, was absolutely void. But as it might be difficult to prove the exact state of the party's mind at the actual celebration of the nuptials, the statute 15 Geo. II. c. 30, has provided, that the marriage of lunatics and persons under phrensies (if found lunatics under a commission, or committed to the care of trustees under any act of parliament), before they are declared of sound mind by the lord chancellor, or the majority of such trustees, shall be totally void.

Idiots and persons of unsound memory, as well as infants and persons under duress, are not totally disabled either to convey or purchase, but *sub modo* only; for their conveyances and purchases are voidable, but not actually void. The king, indeed, on behalf of an idiot, may avoid his grants or other acts. But it has been said, that a *non compos* himself, though he be afterwards brought to a right mind, shall not be permitted to allege his own insanity in order to avoid such grant; because no man shall be allowed to stultify himself, or plead his own disability. The maxim that a man shall not stultify himself, has in fact been handed down as settled law; though later opinions, feeling the inconvenience of the rule, have in many points endeavoured to restrain it. The next heir, or other person interested, may clearly, after the death of the idiot or *non compos*, take advantage of his incapacity, and avoid the grant; and so, too, if he purchases under this disability, and does not afterwards upon recovering his senses agree to the purchase, his heir may either waive or accept the estate at his option. In like manner, an infant may waive such purchase or conveyance when he comes to full age; or, if he does not then actually agree to it, his heir may waive it after him. By the statute 11 Geo. III. c. 20, the guardians or committees of a lunatic are empowered to renew in his right, under the directions of the Court of Chancery, any lease for lives or years, and apply the profits of such renewal for the benefit of such lunatic, his heirs, or executors.

In the law of Scotland, an idiot, or fatuous person, is one entirely deprived of the faculty of reason, having an uniform stupidity and inattention in his manner, and a childishness in his speech, which distinguish him from other men. This state is ascertained by the judgment of a jury, on a brieve directed to the judge-ordinary of the bounds within which the person resides, and containing two heads of inquest; one relating to the state of the person, and the other having for its object to ascertain who is the nearest male agnate of twenty-five years of age. The brieves for cognoscing furious persons are nearly similar, differing only in the description of the circumstances into which the jury are to inquire. As a state of idiocy disqualifies the person for entering into transactions, a proof, even after his death, that the granter of a deed was an idiot at the time of granting it will be sufficient for reducing that deed; and, according to Bankton, restitution on the ground of idiocy is competent to idiots against their curators within four years after their convalescence, in the same way as it is competent to minors.

IDIOM, amongst grammarians, properly signifies the peculiar genius of each language, but is often used in a sense synonymous with dialect. The word is Greek, ἰδιωμα, *propriety*, formed from ἰδιος, *proper, own*.

IDIOPATHY, in *Physic*, a disorder peculiar to a certain part of the body, and not arising from any preceding disease; in which sense it is opposed to sympathy. Thus, an epilepsy is idiopathic when it happens merely through some fault in the brain, and sympathetic when it is the consequence of some other disorder.

IDIOSYNCRASY, amongst physicians, denotes a peculiar temperament of body, by which it is rendered more liable to certain disorders than persons of a different constitution usually are.

IDIOT, or IDEOT, in our laws, denotes a natural fool, or a fool from his birth. See IDIOCY.

The word is originally Greek, ἰδιωτης, which primarily imports a private person, or one who leads a private life, without any share or concern in the government of affairs.

IDIOT is also used, by ancient writers, to signify a person ignorant or unlearned, and answers to *illiteratus*, or *imperitus*. In this sense, Victor tells us, in his *Chronicon*, that in the consulship of Messala, the Holy Gospels, by command of the Emperor Anastasius, were corrected and amended, as having been written by idiot evangelists: *Tanquam ab idiotis evangelistis composita.*

IDLENESS, a reluctance in people to be employed in any kind of work.

Idleness in any person whatsoever is a high offence against the public economy. In China it is a maxim, that if there be a man who does not work, or a woman that is idle, in the empire, somebody must suffer cold or hunger upon that account, the produce of the lands not being more than sufficient, with culture, to maintain the inhabitants; and therefore, though the idle person may shift off the want from himself, yet it must in the end fall somewhere. The court of Areopagus at Athens likewise punished idleness, and exerted a right of examining every citizen as to the manner in which he spent his time; the intention of this being, that the Athenians, knowing they were to give an account of their occupations, should follow only such as were laudable, and that there might be no room left for those who lived by unlawful arts. The civil law expelled all sturdy vagrants from the city; and, in the English law, all idle persons or vagabonds, whom our ancient statutes describe to be "such as wake on the night and sleep on the day, and haunt customable taverns and ale-houses, and routs about; and no man wot from whence they come, ne whether they go;" or such as are more particularly described by the statute 17 Geo. II. c. 5, and divided into three classes, namely, idle and disorderly persons, rogues and vagabonds, and incorrigible rogues; all these are offenders against the good order, and blemishes in the government, of any kingdom. They are therefore all punishable by the statute last mentioned; idle and disorderly persons with one month's imprisonment in the house of correction; rogues and vagabonds with whipping, and imprisonment not exceeding six months; and incorrigible rogues with the like discipline, and confinement not exceeding two years. Persons harbouring vagrants are liable to a fine of forty shillings, and to pay all expenses brought upon the parish thereby; in the same manner as, by our ancient laws, whoever harboured any stranger for more than two nights, was answerable to the public for any offence that might be committed by his inmate.

IDOL, in pagan mythology, an image or fancied representation of any of the heathen gods. This image, of whatsoever materials it might consist, was, by certain ceremonies called consecration, converted into a god; but whilst under the artificer's hand, it was only a mere statue. Three things were necessary to turn it into a god; proper ornaments, consecration, and oration. The ornaments were various, and wholly designed to blind the eyes of the ignorant and stupid multitude. Then followed the consecration and oration, which were performed with great solemnity amongst the Romans. See IMAGE.

IDOLATRY, or the worship of idols, may be distinguished into two sorts. By the first, men adore the works of God, the sun, the moon, the stars, angels, dæmons, men, and animals; by the second, men worship the work of their own hands, as statues, pictures, and the like: but to these may be added a third, that by which men have worshipped the true God under sensible figures and representations. This indeed may have been the case with respect to each of the above kinds of idolatry; thus the Israelites adored God under the figure of a calf.

The host of heaven were the first objects of idolatrous worship, on account of their beauty, their influence on the productions of the earth, and the regularity of their motions, particularly the sun and moon, which are considered as the most glorious and resplendent images of the Deity. But afterwards, when the sentiments of mankind became more corrupt, they began to form images, and to entertain the opinion, that by virtue of consecration, the gods were called down to inhabit or dwell in these statues. Hence Arnobius takes occasion to rally the pagans for guarding so carefully the statues of their gods, who, if they were really present in their images, might save their worshippers the trouble of securing them from thieves and robbers.

As to the adoration which the ancient pagans paid to the statues of their gods, it is certain, that the wiser and more sensible heathens considered them only as simple representations or figures designed to recal to their minds the memory of their gods. This was the opinion of Varro and Seneca; and the same sentiment is clearly expressed in Plato, who maintains that images are inanimate, and that all the honour paid to them has respect to the gods whom they represent. But as to the vulgar, they were stupid enough to believe the statues themselves to be gods, and to pay divine worship to stocks and stones.

IDOMENEUS, in fabulous history, succeeded his father Deucalion on the throne of Crete. He accompanied the Greeks to the Trojan war with a fleet of ninety ships. During this celebrated war he rendered himself famous by his valour, and slaughtered many of the enemy. At his return from the Trojan war, he made a vow to Neptune in a tempest, that if he escaped from the fury of the seas and storms, he would offer to the god whatever living creature first presented itself to his eye on the Cretan shore. This was no other than his own son, who came to congratulate his father upon his safe return. Idomeneus performed his promise to the god; and the inhumanity and rashness of this sacrifice rendered him so odious in the eyes of his subjects, that he left Crete, and having gone in quest of a settlement, landed in Italy, where he founded a city on the coast of Calabria, which he called Salentum. He died in extreme old age, after he had had the satisfaction of seeing his new kingdom flourish, and his subjects happy. According to the Greek scholiast of Lycophron (v. 1217), Idomeneus, during his absence in the Trojan war, intrusted the management of his kingdom to Leucos, to whom he promised his daughter Clisithere in marriage at his return. Leucos at first governed with moderation, but he was persuaded by Nauplius, king of Eubœa, to put to death Meda, the wife of his master, with her daughter Clisithere, and to seize the kingdom. By these violent measures he so strengthened himself on the throne of Crete, that Idomeneus at his return found it impossible to expel the usurper.

IDRIA, a city of the Austrian government of Laybach, in the circle of Adelsburg. It is on the river Idrizza, in a mountainous district, where are some of the richest mines of quicksilver in Europe, which have received greater activity from the neglected state of the similar mines at Almaden in Spain. The city contains 320 houses, with 3650 inhabitants, who are chiefly dependent on the mines for employment. Long. 15. 3. 45. E. Lat. 46. 0. 48. N.

IDSTEIN, a bailiwick of the principality of Nassau, in Germany. It extends over about 82,000 acres, and contains 13,500 inhabitants, of whom about 7000 are Catholics and 6000 Lutherans, with a few Menonites, and some Jews. It contains two cities and twenty-nine villages. The capital is a small city of the same name. It stands at the foot of a mountain, and is surrounded with walls. The inhabitants amount to 1860, employed in curing leather, and other trades. Near to it is the palace of Gassenbach, belonging to the sovereign; and around it his experimental farm, on which are large flocks of Merino sheep.

IDUMÆA. See Edom.

IDYLLION, in ancient poetry, properly signifies any poem of moderate extent, without considering the subject. But as the collection of the poems of Theocritus was called *Idyllia*, and the pastoral pieces being by far the best in that collection, the term *Idyllion* seems to be now appropriated to pastoral pieces.

IF, an island of France, in Provence, and the most eastern of the three before the harbour of Marseilles. It is well fortified, and its port is one of the best in the Mediterranean.

IFSHWAR, a town of Hindustan, in the Mahratta territories, in the province of Malwah, thirty miles south-west from Bopal. Long. 77. 8. E. Lat. 23. 24. N.

IGLAU, a circle of the Austrian province of Moravia, extending over 1110 square miles, comprehending thirty-five cities and towns, 469 villages and hamlets, 23,312 houses, and 146,189 inhabitants. The chief place is a city of the same name, situated on the river Iglawa. It is well built, and surrounded with walls; contains 1200 houses, with 10,986 inhabitants. It is a great manufacturing place, producing yearly from 40,000 to 50,000 pieces of cloth, besides much paper, leather, and other goods. Its situation, on the chief road through the province, furnishes a very considerable transit trade. Long. 15. 30. 55. E. Lat. 49. 23. 23. N.

IGLESIAS, a city in the island of Sardinia, in the province of Cagliari, the see of a bishop. It is finely situated amongst limestone hills, and abundantly watered by various springs; and the surrounding country is highly productive of corn, wine, and fruits. The population in 1826 amounted to 9545 persons.

IGNATIA, a genus of plants belonging to the pentandria class. See Botany, *Index*.

IGNATIUS Loyola, the founder of the order of Jesuits, was born at the castle of Loyola, in Biscay, in the year 1491. He became, first, page to Ferdinand V. king of Spain, and then an officer in the army. In the latter capacity he signalized himself by his valour, and was wounded in both legs at the siege of Pampeluna in 1521. To this circumstance the Jesuits owe their origin; for whilst he was under cure of his wound, a *Life of the Saints*, which was put into his hands, determined him to exchange the military for the ecclesiastical profession. His first devout exercise was to dedicate himself to the blessed virgin as her knight. He then went on a pilgrimage to the Holy Land; and upon his return to Europe he continued his theological studies in the universities of Spain, though he was then thirty-three years of age. After this he went to Paris, and in France laid the foundation of that new order, the institutes of which he presented to Pope Paul III. who made many objections to them, but at last, in 1540, confirmed the institution. The founder died in 1555, and left his disciples two famous books; first, Spiritual Exercises; second, Constitutions or Rules of the Order. But it must be remembered, that though these avowed institutes contain many privileges obnoxious to the welfare of society, the most objectionable are contained in the private rules, entitled *Monita Secreta*, which were not discovered till long afterwards; but most writers attribute these, and even the Constitutions, to Laynez, the second general of the order.

Ignatius, *St*, surnamed *Theophrastus*, one of the apostolical fathers of the church, was born in Syria, educated under the apostle and evangelist St John, and intimately acquainted with some other of the apostles, especially St Peter and St Paul. Being fully instructed in the doctrines of Christianity, he was ordained by St John, and confirmed, about the year 67, bishop of Antioch, by these two apostles, who first planted Christianity in that city, where the disciples also were first called *Christians*. Antioch was then not only the metropolis of Syria, but a city the most renowned of any in the East, and the ancient seat of the Roman emperors, as well as that of the viceroys and governors. In this important see he continued somewhat above forty years, and was both an honour and safeguard to the Christian religion, till the year 107, when Trajan the emperor, flushed with a victory which he had lately obtained over the Scythians and Dacians, about the ninth year of his reign, came to Antioch to make preparations for a war against the Parthians and Armenians. He entered the city with the pomp of a triumph; and as his first care usually was about the affairs of religion, he began presently to inquire into the state of the new faith Christianity had by this time made such progress, that the Romans became jealous and uneasy on account of its advancement. This prince, therefore, had already, in other parts of the empire, commenced a persecution against the Christians, which he now resolved to carry on here. However, as he was naturally of a mild disposition, though he ordered the laws to be put in force against them if convicted, yet he forbade them to be sought after.

In this state of affairs, Ignatius, thinking it more prudent to go himself than wait to be sent for, presented himself to the emperor; and it is said that there passed a long and particular discourse between them, in the course of which the emperor having expressed surprise how he dared to transgress the laws, the bishop took the opportunity to assert his own innocence, and to explain and vindicate his faith and freedom. The issue was, that he was imprisoned, and sentenced to be carried bound by soldiers to Rome, and there thrown as a prey to the wild beasts of the amphitheatre.

He was first conducted to Seleucia, a port of Syria, about sixteen miles distant, where Paul and Barnabas set sail for Cyprus. Having arrived at Smyrna, he paid a visit to Polycarp, bishop of that place, and was himself visited by the clergy of the surrounding country. He also wrote letters to several churches, as the Ephesians, Magnesians, Trallians, and even the Romans, for their instruction and establishment in the faith. He then set sail for Troas, a city of Phrygia, not far from the ruins of old Troy, where, upon his arrival, he was much refreshed with the news he received of the discontinuance of the persecution in Antioch. From Troas he sailed to Neapolis, a maritime town in Macedonia; thence to Philippi, a Roman colony, where the party were entertained with all imaginable kindness, and conducted forwards on their journey through Macedonia and Epirus, till they came to Epidamnium, a city of Dalmatia, where, having again taken shipping, they sailed through the Adriatic, arrived at Rhegium, a port-town in Italy, and directed their course thence through the Tyrrhenian Sea to Puteoli, whence Ignatius desired to proceed by land, ambitious to trace the same way by which St Paul had travelled to Rome. But this wish was not complied with; and, after a stay of twenty-four hours, a prosperous wind quickly carried them to the Roman port, the station of the navy, built near Ostia, at the mouth of the Tiber, about sixteen miles from Rome.

The Christians at Rome, daily expecting his arrival, came out to meet him, and received him with a mixture of joy and sorrow; but when some of them intimated that possibly the populace might be diverted from desiring his death, he expressed a pious indignation, entreating them to cast no obstacles in his way, nor do any thing that might tend to deprive him of that crown of martyrdom to which he ardently aspired. There are many such expressions as this in his epistle to the Romans, yet it does not appear that he rashly sought or provoked danger. Being conducted to Rome, he was presented to the prefect; and the emperor's letters concerning him were also delivered. The interval before his martyrdom was spent in prayers for the peace and prosperity of the church. That his punishment might be the more public, one of their solemn festivals, the time of the Saturnalia, and that part of it when they celebrated the Sigillaria, was fixed for his execution. Accordingly, on the 20th of December, he was brought out into the amphitheatre, and the lions being let loose, quickly despatched him, leaving nothing but a few of the hardest of his bones. These remains were gathered up by two deacons who had been the companions of his journey; and being transported to Antioch, were interred in the cemetery, without the gate which leads to Daphne.

St Ignatius stands at the head of those Anti-Nicene fathers who occasionally delivered their opinions in defence of the divinity of Christ, whom he calls the *Son of God, and his eternal word.* He is also reckoned the great champion of the doctrine of the episcopal order, as distinct from and superior to that of priest and deacon; and one, the most important, use of his writings respects the authenticity of the Holy Scriptures, which he frequently alludes to in the very same expressions which we find at this day. Archbishop Usher's edition of his works, printed in 1647, is thought the best; yet there is a more recent edition published at Amsterdam, where, besides the best notes, there are the dissertations of Usher and Pearson.

St Ignatius's Bean, the fruit of a plant. See Ignatia, Botany.

IGNIS Fatuus, a kind of light, supposed to be of an electrical nature, appearing frequently in mines, marshy places, and near stagnant waters. It was formerly thought to have something ominous in its nature, and to presage death and other misfortunes. There have been instances of people being decoyed by these lights into marshy places, where they perished; and hence the names of *Ignis fatuus, Will-with-a-wisp*, and *Jack-with-a-lanthorn*, as if this appearance were an evil spirit which took delight in doing mischief of that kind. The general opinion is, that this light is produced by the decomposition of animal or vegetable matters, or by the evolution of gases which spontaneously inflame in the atmosphere.

IGNITION properly signifies setting fire to any substance; but the sense is sometimes limited to that kind of burning which is not accompanied with flame, such as that of charcoal, cinders, metals, stones, and other solid substances. For the explanation of the phenomena of ignition, see Chemistry.

IGNOBILES, amongst the Romans, was the designation of those persons who had no right of using pictures and statues. See Jus Imaginis.

IGNOMINIA, a species of punishment amongst the Romans, by which the offender suffered public shame, either by virtue of the prætor's edict, or by order of the censor. This punishment, besides the disgrace, deprived the party of the privilege of bearing any offices, and of almost all the other rights of a Roman citizen.

IGNORAMUS, in *Law*, is a word properly used by the grand inquest impannelled in the inquisition of causes criminal and public, and written upon the bill, by which any crime is offered to their consideration, when they mislike the evidence, as defective, or too weak to make good the presentment; the effect of which word so written is, that all further inquiry for that fault is thereby stopped, and the party delivered without further answer. It resembles that custom of the ancient Romans, where the judges, when they absolved a person accused, wrote *A.* upon a little table provided for that purpose, meaning thereby *absolvimus;* but if they judged him guilty, they wrote *C.* for *condemnamus;* and if they found the cause difficult and doubtful, they wrote *N. L.* for *non liquet.*

IGNORANCE, the privation or absence of knowledge. The causes of ignorance, according to Locke, are chiefly these three; first, want of ideas; secondly, want of a discoverable connection between those ideas we have; and, thirdly, want of tracing and examining our ideas.

Ignorance, in a more particular sense, is used to denote want of learning.

Ignorance, or mistake, in *Law*, a defect of will, by which a person is excused from the guilt of a crime, when, intending to do a lawful act, he does that which is unlawful. For here the deed and the will acting separately, there is not that conjunction between them which is necessary to constitute a criminal act. But this must be an ignorance or mistake of fact, and not an error in point of law. For a mistake in point of law, which every person of discretion not only may, but is bound and presumed to know, is, in criminal cases, no sort of defence. *Ignorantia juris, quod quisque tenetur scire, neminem excusat*, is as well the maxim of our own law as it was of the Roman.

IGUALADA, a town of Spain, in the province of Catalonia, with 12,000 inhabitants. It is situated near the celebrated monastery of Montserrat, and has a strong castle, which was long occupied by the French during the Peninsular war. It has a very large manufactory of firearms. Lat. 41. 35. N.

IKERY, formerly a town of the south of India, and province of Mysore, of great note, and said by the natives, with their usual exaggeration, to have contained 100,000 inhabitants. It was for a long period the residence and capital of a dynasty of Hindu princes, whose coins are still in existence. It is now in ruins, not, however, from the devastation of war, or any other calamity, but merely from the removal of the court to Bednore. Long. 76. 7. E. Lat. 14. 6. N.

ILA, Ilay, or Islay, a large island belonging to Argyleshire, and the most southerly of those called the Hebrides. It lies in a westerly direction from the peninsula of Kintyre, distant from it about twelve miles, and is separated on the north from the island of Jura by a small channel. It is twenty-eight miles in length, and at the broadest measures eighteen miles across. Oats and barley are the principal crops raised, and much of the grain is used in the distillation of whisky, for which the island is celebrated. There are about fourteen distilleries upon it, and the trade thus carried on has been the means of greatly improving the condition of Islay. In 1821 the population amounted to 11,008, and in 1831 to 19,780. See SCOTLAND.

ILANCE, a town of Switzerland, in the canton of the Grisons. Though small, it is a kind of capital, being the place where the authorities of the canton assemble. It is in a most picturesque situation, at the foot of a mountain, where the river Glenner falls into the Rhine. It has little or no trade, and the population scarcely amounts to 1000. It is, however, a city, being surrounded with walls.

ILBESSAN, a city of European Turkey, the capital of the circle of that name, in the province of Rumelia. It is situated on the river Uschkowobin, on a fruitful plain, is the seat of a Greek bishop, has a castle which repelled the attacks of Scanderbeg, and 3000 inhabitants.

ILCHESTER, a small borough town of the county of Somerset, in the hundred of Tintinhull, 122 miles from London. It stands upon the river Ivel, one of the branches of the Parel, which is navigable within three miles of the town. It was once a fortified city, and the remains of the Roman fortifications may still be traced. It is the town where county elections are held, where the jail stands, and where criminals are executed; but the assizes are removed to the larger towns, Wells, Taunton, and Bridgewater. It formerly returned two members to the House of Commons, chosen by the householders, but was disfranchised in 1832. It is remarkable as the birth-place of Roger Bacon. There is a small market on Wednesday. The inhabitants amounted in 1801 to 817, in 1811 to 610, in 1821 to 802, and in 1831 to 1095.

ILDEFONSO, a town of Spain, in the province of Segovia. It is situated on the northern declivity of the Guadarama Mountains, 3000 feet above the level of the sea. It contains about 5000 inhabitants, who are mostly employed in making glass in a royal manufactory, which during the Peninsular war was abandoned, but has since been re-established. It was long celebrated for the large size of the mirrors fabricated in it, some of which were twelve feet high and seven feet wide. Here is also a royal palace, generally inhabited by the court in the few hottest months of summer. This palace, called the Granja, from having been originally a barn, has been highly decorated by a valuable gallery of pictures, and many other curiosities. It has also a fine garden laid out in the French taste, and embellished with all kinds of water-works, resembling those constructed at Versailles, but superior, from the river Eresma, which supplies them, descending with great rapidity from the mountain. This place is about forty miles north-west from Madrid, and six miles from Segovia.

ILERDA, in *Ancient Geography*, the capital of the Iligertes, situated on an eminence between the rivers Sicoris and Cinga; a city often besieged and often taken, because exposed to incursions from Gaul, and under Gallienus destroyed by the Germans. Ilerda, now Lerida, on the river Segre.

ILEX, the holm or holly-tree, a genus of plants belonging to the tetrandria class, and in the natural method ranking under the forty-third order, *Dumosæ*. See BOTANY.

ILFORD, a hamlet properly, but really a town, of the county of Essex, in the hundred of Beacontree. It is within the parish of Barking, but is a chapelry, with its own church. It stands on the great road from London to Yarmouth and Ipswich, at the distance of seven miles from Whitechapel church. The river Roding runs through it in its way to the Thames, in several branches, over which bridges are thrown. The population amounted in 1801 to 1724, in 1811 to 2462, in 1821 to 2972, and in 1831 to 3512.

ILFRACOMBE, a port and market-town of the county of Devon, 202 miles from London, in the hundred of Braunton. It is situated on the Bristol Channel, with a good harbour, but dry at low water. It is much visited for sea bathing, and is the principal passage from Devonshire to South Wales. The inhabitants amounted in 1801 to 1838, in 1811 to 1934, in 1821 to 2622, and in 1831 to 3201.

ILIAC PASSION, a violent and dangerous kind of colic, which takes its name from the intestine ilion, on account of its being usually affected in this distemper; or perhaps from the Greek verb εἰλεῖν, *to wind* or *twist;* and hence also it is by the Latins called *volvulus*. See MEDICINE.

ILIAD, the name of an ancient epic poem on the subject of the taking of Troy, being the first and best of the epics composed by Homer. The Iliad is divided into twenty-four books or rhapsodies, which are marked with the letters of the alphabet.

ILIMSK, a town of Asiatic Russia, situated on the Ilim, which falls into the Anguri. In the environs are found the most beautiful black sables. It contains 107 houses, and 531 inhabitants. It is 152 miles north of Irkutsk.

ILISSUS, a river to the east of Athens, which, uniting with the Eridanus on the west side, falls into the sea below the city. It was sacred to the muses, called *Iliassides;* and on its bank stood their altar, where the lustration in the lesser mysteries was usually performed.

ILIUM, or ILION, in *Ancient Geography*, a name for the city of Troy, but most commonly used by the poets, and distinguished by the epithet *Vetus*, ancient. According to Strabo, the ancient city was thirty stadia farther east than New Ilium. The position of the latter is, according to Dr Clarke, upon a low eminence, about three miles from the promontory Sigeum, now called Jenitchere. New or modern Ilium was a village which Alexander, after the battle of Granicus, called a city, and ordered to be enlarged. It was afterwards adorned by the Romans, who granted it immunities as their mother city. The various disasters of the Greeks and Trojans, as described by Homer, gave rise to the proverb *Ilias Malorum*.

ILKESTON, a town of the county of Derby, in the hundred of Morleston and Litchurch, 126 miles from London. It is a place of manufacturing industry. The population amounted in 1801 to 2422, in 1811 to 2970, in 1821 to 3681, and in 1831 to 4446.

ILLECEBRUM, a genus of plants belonging to the pentandria class, and in the natural method ranking under the twelfth order, *Holoraceæ*. See BOTANY.

ILLE-VILAINE, a department of the north of France, on the sea coast, formed out of a part of the ancient province of Normandy. It extends in north latitude from 47. 39. to 48. 42. and in west longitude from 1. 13. to 2. 16. It is bounded on the north by the English Channel, on the east by the department of Mayenne, on the south by the Lower Loire, and on the west by Morbihan and the Lake du Nord. It is 2756 square miles in extent, and is divided into six arrondissements, which are subdivided into forty-three cantons and 352 communes. The population, according to the Annuaire for 1834, amounted to 547,052 individuals. They almost exclusively adhere to the Romish church, as the few Protestants are in no place sufficiently numerous to form a congregation. They are for the most part of a Celtic race, and speak a language much like that of the Welsh; and though some French words have been introduced, they are scarcely intelligible by the French people. Those on the sea coast are employed in the fisheries, and in the numerous small craft make excellent sailors. The inland inhabitants are much attached to their ancient customs, are uninstructed, and most superstitious. They live much on food composed of buck-wheat, made into a kind of pudding called *galettee*; and chestnuts form a material part of their sustenance. The country people are ill clad, generally with domestic manufactures. The estates are much divided; a farm of sixty acres is deemed a large one, and the far greater number do not exceed twelve acres. Hence they are for the most part excessively poor, and, particularly in winter, suffer much hardship. The face of the country is generally level, but with a few slight undulations. The highest of these hills are in the arrondissement of Fougeres on the east, and in that of Montfort to the west. The coast is surrounded with cliffs, and with small rocky projections; and on the borders there are artificial dams, constructed to prevent the encroachments of the sea. The rivers which give their name to the department neither rise within it, nor do they discharge their waters into the sea till they enter the adjoining province of Morbihan. The Vilaine is navigable for vessels of 200 tons by help of the tide, up to Vitrè, from whence is a communication by a canal with the town of Rance.

The soil is unfavourable to cultivation, scarcely exceeding an inch in depth, and resting on a bed of clay or slaty stone. Much of the land is covered with morasses and swamps, which, with the woods and heaths, leaves but little for agriculture, though on the sides of the rivers there is some tolerably good pasture land. The department scarcely grows sufficient corn for the inhabitants, though they use most of the lowest description. Hemp and flax are grown, and chiefly used at home. Fruit trees are abundant and productive. Some horses are bred for sale to other districts, and some cows are kept for the dairy; but the breed of sheep is much neglected. There is little trade, and few manufactures; the latter are limited to twine and sail-cloth. There is very little wine made, but abundance of cedar. The cities and towns are small. The only ones having more than 4000 persons are, the capital, Rennes, with 29,680; Fougeres, with 7677; Saint Malo, with 9890; Vitrè, with 8856; and Redon, with 4504.

ILLICIUM, a genus of plants belonging to the dodecandria class, and in the natural method ranking with those of which the order is doubtful. See BOTANY.

ILLINOIS, one of the United States of North America, is bounded on the north by the territory of Huron; on the east by Lake Michigan and the state of Indiana; on the south by the Ohio river, which separates it from Kentucky; and on the west by the Mississippi, which separates it from the state and territory of Missouri. It lies between lat. 37° and 42° 30′ north, and long. 87° 20′ and 91° 20′ west, being about 380 miles in length from north to south, and 210 miles in width from east to west, and comprehending an area of 58,900 square miles. Next to Louisiana and Delaware, this is considered as the most level state in the Union. There are a few hills, and some elevations that might be designated mountains; but by far the greater portion of the state consists of beautiful and fertile prairies, finely diversified with wood. These prairies or meadows, which are sometimes of vast extent, are distinguished by the names of wet and dry, alluvial and rolling. The wet prairies contain peat, logs of wood, and exhibit other indications of their having once been morasses in which wood grew. The origin of many of the rivers is to be traced to these prairies. Those of an alluvial nature are high and dry, of a rich black loam, which is exceedingly fertile; and they are covered with a coarse kind of grass, which grows to an enormous size. The high and rolling prairies are sometimes chequered with groves of sparse trees. Their soil is in general only of second rate quality, and they abound in springs. Grape vines are abundant; and they furnish an inexhaustible summer range for cattle. From the exceeding flatness of some of the plains, and their consequent want of inclination, the rain that falls is not carried off, but allowed to remain and stagnate, so that such situations are very unhealthy. Grand Prairie is the largest tract of land of this description. The first stratum of soil is a black, friable, and sandy loam, from two to five feet in thickness. The next is a red clay mixed with fine sand, and from five to ten feet in thickness. The third is a hard blue clay, of a beautiful appearance and greasy feel, mixed with pebbles, and, when exposed to the air, capable of emitting a fetid odour. This soil is of the first quality, and here the springs are found. Strawberries are raised in immense quantities, and of the very finest quality. Timber, however, is scarce, and good water is likewise deficient.

Between Carlisle and St Louis a tract of country fifty miles in extent, woods, streams, hills, limestone ledges, and a rolling country, present themselves. The hills here abound in stone coal, and limestone is also plentiful. A range of hills commences at the bluffs which bound the "American bottom," near Kaskaskia, and stretches north-eastwardly through the state towards Lake Michigan. Another limestone bluff breaks off almost at right angles to this chain, and stretches along the margin of the American bottom to the point nearly opposite the Missouri. This bluff has in many places a regular front of perpendicular limestone, not unfrequently 300 feet in height. There are other chains of bluffs, which are marked by the same grand natural features. The American bottom commences not far below Kaskaskia, and stretches eighty miles along the shores of the Mississippi. It is from three to six miles in width, and forms two belts, the one, which borders the Mississippi, having a heavy timbered bottom, and the other, which reaches the foot of the perpendicular bluffs, being prairie of the richest quality. For above one hundred years crops of maize have been raised on some parts of this tract, without the slightest exhaustion of soil having become apparent. Vegetation here flourishes most luxuriantly; but there is a counterbalance in the unhealthiness of the climate, particularly during autumn. On either bank of the Illinois, almost from its mouth to its source, there is a similar bottom, with bluffs and chains of hills similar to the preceding. The military bounty tract, which is distributed amongst the soldiers of the late war, commences in the neighbourhood of Lower Alton. It comprehends the north-west corner of the state, about 170 miles long and sixty broad, and is situated between the rivers Mississippi and Illinois. This district of country has great advantages; the soil is rich and extremely fertile, and much of the prairie ground is eminently beautiful; but the situation is unhealthy. Not only in this state, but over all the western territory, the lands seem to be distributed in bodies, either of rich or sterile, or of level or broken lands. On Rock River, the Illinois, the Kaskaskia, Embarras, between the Big and Little Wabash, on the Parassaw, the Macoupin, the Sangamon, and on all the other considerable streams of this state, there are very large tracts of first-rate land. The Grand Prairie, the Mound Prairie, the prairie upon which the marine settlement is fixed, and that occupied by a society of Christians from New England, are all exceedingly rich. The Sangamon district of country, in particular, presents a happy proportion of timbered and prairie lands, and a soil of great fertility, whilst accounts from various quarters concur in representing it as more healthy than any other part of the state. The prevailing trees are, the locust, black walnut, and pecean; and there is a vast summer range for cattle. Iron and copper ore, salt springs, gypsum, and stone coal, are abundant; and the whole district is now divided into a number of populous counties, and is thickly settled by thriving farmers. Along the course of the Kaskaskia or Okau, tracts of land equally extensive and fine are stretched. This river has a long course through the central parts of the state, and a country beautifully diversified with hill, vale, prairie, and forest. On its banks is Kaskaskia, formerly the seat of government; and Vandalia, at present the metropolis. A late traveller (Stuart, *Three Years in North America*, vol. ii. p. 379) thus speaks of Illinois: "The general description of the state of Illinois is, that it contains 58,900 square miles; is the fourth state in point of extent in the union, only inferior in this respect to Virginia, Georgia, and Missouri, with a general level, not varying above sixty feet; and that it consists, with little interruption, of one vast prairie of admirable soil, extending from the Mississippi to Lake Michigan. It is the richest country in point of soil in the world. The French called it the terrestrial paradise."

Count Marbois thus writes of this country generally: "At the junction of the Mississippi and Missouri, the lands lying towards the north-west are of admirable fertility. Emigration already inclines there; and these districts, though very remote from the sea, will one day be as well peopled as any other country in the world. The Mississippi, the Missouri, the Arkansas, and the Red River, and their tributaries, water 200,000 square leagues within the space of country called the basin of the Mississippi. This internal navigation, prepared by nature, has already been wonderfully extended and improved by canals, excavated by the labour of man; and steam-boats descend and ascend against wind and tide, brave the most rapid currents with more speed, and with more convenience, than the finest roads in Europe can be travelled. Wood and coal, indispensable agents in this navigation, abound on the shores of the rivers; and the steam-engine has put an end to the difficulty of communication, heretofore one of the greatest obstacles that were ever opposed to the improvement of colonies."

Illinois is particularly fortunate, not only in the number, but in the navigability, of its rivers. For a great distance on its northern extent it has the waters of Lake Michigan, and the boatable streams that are therein discharged; and by this means a communication is opened with the northern fronts of Indiana and Ohio, with New York and Canada. On the north-west is Rock River, a long, beautiful, and boatable tributary of the Mississippi. Its whole western front is washed by the latter river, and its northern by the Ohio. On the east is the Wabash, which has a course of about 130 miles, the greater part of it being navigable; and through its centre winds in one direction the Illinois, which connects the Mississippi with Lake Michigan by the Plein and Kankakee, whilst in another direction the Kaskaskia traverses the state for a distance of between 200 and 300 miles. At present the state is supposed to include 4000 miles of boatable waters within its limits. The Illinois, which gives name to the state, may be considered as the most important river in North America, having its whole course within one state. It is formed by the junction of two other rivers in the north-west part of Indiana, and, passing into Illinois, pursues generally a south-westerly direction, and flows into the Mississippi twenty-one miles above the Missouri. It is upwards of 400 yards wide at its mouth, is about 400 miles long, and is of easy navigation. Its current, which is very gentle, is unbroken by falls or rapids, and it passes through a fine country.

In this state there are prodigious lead mines, as well as those of coal and lime. There is also building stone in the bounty tract. Specimens of native malleable copper have been found, weighing from one to three pounds. On the Saline River, a branch of the Ohio, are salt springs, from which salt is manufactured at a cheap rate. About 300,000 bushels of this article are annually made. The lead mines are situated at Galena, on Fever River, near the north-west corner of the state. The working of them commenced in 1821, and in 1824 there were made 175,220 lbs. of lead. In the year 1829 the produce had amounted to 13,343,150 lbs.

The prevailing forest tree in Illinois is oak, of which thirteen or fourteen different species are enumerated. Throughout the territory there are also found honey locust, black walnut, mulberry, plum, sugar maple, black locust, elm, bass-wood, beech, buck-eye, hack-berry, coffee-nut, sycamore, spice-wood, sassafras, black and white haws, crab-apple, wild cherry, cucumber, and pawpaw. White pine is found on the head branches of the Illinois. The chief produce of the state is Indian corn, wheat, and the other agricultural productions of North America. From the extent and fertility of the soil, those articles which it is best adapted for are raised in far greater quantities than are requisite for the home consumption of the state. The immense prairies afford abundance of food for cattle, and grazing is extensively carried on. Great numbers of fine cattle and horses are regularly sent to New Orleans. Most of the clothing of the people is of domestic manufacture. The climate of Illinois does not materially differ from that of the same latitudes in the Atlantic states. The low and wet lands in the southern part are unhealthy, and the cold of winter is in some parts exceedingly severe. Amongst the diseases which afflict this state is one called the *milk sickness*, with which cows are seized, particularly in autumn, when the first severe frost begins. It is supposed to be occasioned by the eating of a luxuriant poisonous vine, to which the animals are compelled at this season of the year to have recourse for sustenance. Milk taken in any quantity seems to produce the same disease in other animals, and even in men, and it very often proves fatal.

We shall now describe a few of the principal towns of this state. Vandalia, the political metropolis, is pleasantly situated on a high bank of the Kaskaskia river, in the centre of a rich and thriving country. Although only founded a few years since, it contains many handsome brick buildings; and respectable houses for the accommodation of the government and the courts have also been erected. Edwardsville, on Cahokia Creek, twenty miles north-east from St Louis, is a county town of some consequence, and was, until within a few years, the seat of government. Belleville is in the centre of Turkey Hill settlement, eighteen miles south-east of St Louis, and a few miles east of the American bottom. It is a flourishing village, in the midst of a compact settlement, and most excellent lands. Alton is a new village, a little above the mouth of the Missouri. Its position is favourable, the situation is healthy, and it promises to become a considerable town. Carlisle is situated on the western bank of the Kaskaskia, on the great road from Cincinnati to St Louis. Boats of burthen can ascend the river to this place when the water is favourable. Cahokia is situated in the American bottom, on a creek of the same name, a few miles below St Louis. It is one of the most ancient villages in the county, is of considerable extent, and chiefly inhabited by French. There is another French village of about the same size, called Prairie du Rocher. It is situated near a most beautiful limestone bluff, twelve miles above Kaskaskia. Kaskaskia is situated on an extensive plain, not far from the commencement of the American bottom, eleven miles from the mouth of the river on which it stands, and six miles from the nearest point of the Mississippi. This town was one of the first establishments made by the French in the valley of the Mississippi, and is a place of higher antiquity than Philadelphia. It was once of greater importance than it is at present, the inhabitants, which were formerly 7000 in number, being now reduced to 1000. It is beautifully situated in the centre of a gently sloping basin, on a fine navigable stream, and in the midst of a country proverbial for its fertility. It is the seat of justice for the county to which it belongs, and has a bank, a printing-office, a Catholic church, and a land-office. At about three hundred miles west from Vandalia stands Galena, which owes its origin to the rich lead mines in the vicinity. It contains forty-two stores and warehouses, between 200 and 300 dwelling-houses, and 1000 inhabitants. There is here a weekly journal, and the usual concomitants of a county seat. About 10,000,000 pounds of lead are annually exported from this place. The population in the vicinity is estimated at 10,000. Shawneetown is situated on the Ohio, nine miles below the mouth of the Wabash. The great United States Saline, situated twelve miles from this town, contributes to give it consequence. It is the seat of justice for its county, and has a bank with a large capital, and a land-office. Besides these, there are a number of towns or villages, which, however, do not require particular notice.

The territory of Illinois was formed into a state and admitted into the Union in 1818. By the constitution no more slaves can be admitted into the state. The legislative power is vested in a general assembly, consisting of a senate and a house of representatives. The senators are chosen for periods of four years, and the representatives biennially. The executive power is vested in a governor, who is chosen for four years, and is ineligible for the succeeding four years. There is a supreme court established by the constitution, and there are inferior courts established by the general assembly. The judges who are appointed by the assembly hold their places during good behaviour, but can be removed by the governor on an address of two thirds of each branch of the general assembly. Schools are supported by a grant of land amounting to a thirty-sixth part of each township; and three per cent. of the net proceeds of the United States' lands sold within the state is appropriated for the encouragement of learning, of which a sixth part is required to be bestowed on a college or university. A further provision has been made for a university, by the grant of two townships of land by the United States. Illinois college, situated at Jacksonville, was founded in 1829, and has a fund of 13,000 dollars.

Though this state is in general favourable for the construction of roads, yet the low and clayey prairies are exceptions. Rivers furnish the most convenient means of transport, and various canals, which will make up for any deficiency, are in contemplation. It is also proposed to extend the national road from Indianapolis to Vandalia, and thence to St Louis. The history of this state forms part of that of Louisiana, under which head it will be given. With regard to the native Indians, they have by different treaties ceded the greater part of their territorial claims to lands; and those who still roam at large are rarely seen, excepting on the skirts of the state, in the character of hunters, or of vagrants. This state is divided into forty-eight counties, and the census of 1830 gives the population as follows: Whites, 155,176; slaves, 746; making the total 157,575. The number of inhabitants has been tripled in ten years. (R. R. R.)

ILLOGAN, a town of the hundred of Penwith, in the county of Cornwall, 266 miles from London. It is in a mining district, which affords employment to the people, especially in one of the richest of the copper mines, called Cook's Kitchen, which is within the parish. The inhabitants amounted in 1801 to 2895, in 1811 to 4078, in 1821 to 5170, and in 1831 to 6072.

ILLUMINATI, the name of a secret society or order in Germany and other countries of Europe, whose professed object, it is said, was to propagate the purest principles of virtue; but whose real views were to subvert every established government and religion, and, by delivering mankind from the necessary and salutary restraints of civil society, to bring them to an imaginary state of freedom and independence. Of this order much has been said and written; but that any society existed, regularly organized in the way which this is represented to have been, working in secret, and at the same time possessing extensive power and influence, has not been established by any kind of proof.

ILLUMINATING, a kind of miniature painting, anciently much practised for illustrating and adorning books. Besides the writers of books, there were artists whose profession it was to ornament and paint manuscripts, and who were called illuminators. The writers of books first finished their part, and the illuminators embellished them with ornamented letters and paintings. We frequently find in manuscripts blanks left for the illuminators, which, however, were never filled up. Some of the ancient manuscripts were gilt and burnished in a style superior to those of later times. The colours were excellent, and the skill in preparing them must have been very great.

The practice of introducing ornaments, drawings, emblematical figures, and even portraits, into manuscripts, is of great antiquity. Varro wrote the lives of seven hundred illustrious Romans, which he enriched with their portraits, as Pliny attests (*Hist. Nat.* lib. xxxv. chap. 2). Pomponius Atticus, the friend of Cicero, was the author of a work on the actions of the great men amongst the Romans, which he ornamented with their portraits, as we are informed by Cornelius Nepos in his life of that illustrious Roman. But these works have not been transmitted to posterity. There are, however, many precious documents remaining, which exhibit the advancement and decline of the arts in different ages and countries. These inestimable paintings and illuminations display the manners, customs, habits ecclesiastical, civil, and military, weapons and instruments of war, utensils and architecture, of the ancients; and they are of the greatest use in illustrating many important facts relative to the history of the times in which they were executed. In these treasures of antiquity are preserved a great number of specimens of Grecian and Roman art, which were executed before the arts and sciences fell into neglect and contempt. The manuscripts containing these specimens form a valuable part of the riches preserved in the principal libraries of Europe; the Royal, Cottonian, and Harleian Libraries, as also those in the two universities of England, the Vatican at Rome, the Imperial at Vienna, the Royal at Paris, St Mark's at Venice, and many others.

A very ancient manuscript of Genesis, which was in the Cottonian Library, and almost destroyed by a fire in 1731, contained two hundred and fifty curious paintings in water-colours. Twenty-one fragments, which escaped the fire, have been engraved by the Society of Antiquaries of London. Several specimens of curious paintings also appear in Lambecius's catalogue of the Imperial Library at Vienna, particularly in volume third, where forty-eight drawings of nearly equal antiquity with those in the Cottonian Library are engraven; and several others may be found in various catalogues of the Italian libraries. The drawings in the Vatican Virgil, executed in the fourth century, before the arts were entirely neglected, illustrate the different subjects treated of by the Roman poet. A miniature drawing is prefixed to each of the gospels brought over to England by St Augustin in the sixth century, which is preserved in the library of Corpus Christi College, Cambridge. In the compartments of those drawings are depicted representations of several transactions in each gospel. The curious drawings and elaborate ornaments in St Cuthbert's gospels, made by St Ethelwald, and now in the Cottonian Library, exhibit a striking specimen of the state of the arts in England in the seventh century. The same observation may be made respecting the drawings in the ancient copy of the four gospels preserved in the cathedral church of Lichfield, and those in the *Codex Rushworthianus* in the Bodleian Library at Oxford. The life of St Paul the Hermit, now remaining in Corpus Christi College, Cambridge, affords an example of the style of drawing and ornamenting letters in England in the eighth century; and the copy of Prudentius's *Psycomachia* in the Cottonian Library exhibits the style of drawing in Italy in the ninth century. Of the tenth century there are Roman drawings of a singular kind in the Harleian Library, No. 2820; whilst Nos. 5280, 1802, and 432, in the same library, contain specimens of ornamented letters, which are to be found in Irish manuscripts from the twelfth to the fourteenth century. Cædmon's Poetical Paraphrase of the book of Genesis, written in the eleventh century, which is preserved amongst Junius's manuscripts in the Bodleian Library, exhibits many specimens of utensils, weapons, instruments of music, and implements of husbandry, used by the Anglo-Saxons. The like may be seen in extracts from the Pentateuch of the same age in the Cottonian Library. The manuscript copy of Terence in the Bodleian Library displays the dresses, masks, &c. worn by comedians in the twelfth century, if not earlier. The very elegant Psalter in the library of Trinity College, Cambridge, exhibits specimens of the art of drawing in England in the same century. The Virgil in the Lambeth Library of the thirteenth century, and written in Italy, shows, both by the drawings and writing, that the Italians produced works much inferior to ours at that period. The copy of the Apocalypse, in the same library, contains a curious example of the manner of painting in the fourteenth century. The beautiful paintings in the history of the latter part of the reign of King Richard II., in the Harleian Library, afford curious specimens of manners and customs, both civil and military, at the close of the fourteenth and in the beginning of the fifteenth century. Many other instances might be produced; but those who desire further information may consult Strutt's *Regal and Ecclesiastical Antiquities*, and his *Horda Angelcynnan*, published in three volumes.

This art was much practised by the clergy, and even by some in the highest stations in the church. "The famous Osmund," says Bromton, "who was consecrated Bishop of Salisbury, A. D. 1076, did not disdain to spend some part of his time in writing, binding, and illuminating books." Mr Strutt, as already noticed, has given the public an opportunity of forming a judgment as to the degree of delicacy and art with which these illuminations were executed, by publishing prints of a prodigious number of them, in his *Regal and Ecclesiastical Antiquities of England*, and his *View of the Customs of England*. In the first of these works we are presented with the genuine portraits, in miniature, of all the kings and several of the queens of England, from Edward the Confessor to Henry VII. mostly in their crowns and royal robes, together with the portraits of many other eminent persons of both sexes.

The illuminators and painters of this period seem to have been in possession of a considerable number of colouring materials, and to have known the arts of preparing and mixing them, so as to form a great variety of colours; for, in the specimens of their miniature-paintings which are still extant, we perceive not only the five primary colours, but also various combinations of these. Though Strutt's prints do not exhibit the bright and vivid colours of the originals, they give us equally a view, not only of the persons and dresses of our ancestors, but also of their customs, manners, arts, and employments, their arms, ships, houses, and furniture, and enable us to judge of their skill in drawing. The figures in these paintings are often stiff and formal; but the ornaments are in general fine and delicate, and the colours clear and bright, particularly the gold and azure. In some of these illuminations the passions are strongly represented. Terror, for example, is strongly painted in the faces of the Earl of Warwick's sailors when they were threatened with a shipwreck, and grief in the countenances of those who were present at the death of that hero. After the introduction of printing, this elegant art of illuminating gradually declined, and at length became quite neglected.

Before concluding, it may not be improper to observe, that from the fifth till the tenth century, the miniature paintings which we meet with in Greek manuscripts, are generally good, as are also some which we find amongst those of Italy, England, and France. From the tenth till the middle of the fourteenth century they are commonly very bad, and may be considered as so many monuments of the barbarism of those ages; but towards the latter end of the fourteenth, the paintings in manuscripts were much improved; and in the two succeeding centuries many excellent performances were produced, especially after the restoration of the arts, when great attention was paid to the works of the ancients, and the study of antiquity became fashionable.

ILLUMINATORS. See ILLUMINATING.

ILLUMINED, ILLUMINATI, a term anciently applied to such persons as had received baptism. This name was occasioned by a ceremony in the baptism of adults, which consisted in putting a lighted taper in the hand of the person baptized, as a symbol of the faith and grace which he had received in the sacrament.

ILLUMINED, *Illuminati*, is also the name of a sect of heretics who sprang up in Spain about the year 1575, and were called by the Spaniards *Alambrados*. Their principal doctrines were, that by means of a sublime manner of prayer, which they had attained to, they entered into so perfect a state, that they had no occasion for ordinances, sacraments, or good works; and that they could give way even to the vilest actions without sin. The sect of Illumined was revived in France in the year 1634, and was soon afterwards joined by the Guerinets, or disciples of Peter Guerin, who together formed but one body, called also *Illumined;* but being hotly pursued by Louis XIII. they were soon destroyed. The brothers of the Rosy Cross are sometimes also called *Illumined*. See ROSYCRUCIAN.

ILLUSTRIOUS, ILLUSTRIS, in the Roman empire, a title of honour peculiar to people of a certain rank. It was first given to the most distinguished amongst the knights, who had a right to bear the *latus clavus;* but afterwards those only were entitled *illustrious* who held the first rank amongst the persons called *honorati*, that is, the *præfecti prætorii*, *præfecti urbis*, treasurers, comites, and others. The Novels of Valentinian distinguish as many as five kinds of *illustres*, amongst whom the *illustres administratores* bear the first rank.

ILLYRIA, or ILLYRICUM, ANCIENT, a country situated on the east coast of the Adriatic, the limits of which were at no time distinctly marked. In its most restricted sense it may be considered as extending from Dalmatia on the north, to Epirus on the south, from which it was separated by the Acroceraunian range of mountains. To the east it was separated from Macedonia by a lofty chain of mountains, which was known under the several names of Bertiscus, Scardus, *Tschar Dagh*, and Bernus. When the Romans conquered the country, they added to it the Dalmatians, Japydes, and other petty tribes; and, under the emperors, so widely were the frontiers of Illyria extended, that it comprehended the great districts of Pannonia, Rhætia, Noricum, and Mœsia (Appian, *Illyr.* 6). In the third century we find *Duces totius Illyrici* mentioned, under whose command were placed not only the troops of the above-mentioned countries, but also those of Thrace. When the Roman empire was divided into two parts, they each received a portion of Illyria. The western portion comprehended Dalmatia, Pannonia, and Noricum, and belonged to the *Præfectus prætorio Italiæ.* It is remarked by Strabo (vii. 317), that the coast of Illyria presented everywhere good harbours, whilst the opposite side of Italy was entirely devoid of them. The climate was excellent, and the soil in general such as to produce olive trees and vines. In the interior, however, the country is mountainous, and covered with snow during a great part of the year.

Illyria was inhabited by a great number of different tribes, of whom we shall mention the principal. In the north were the Japydes, the Liburni, celebrated as a maritime people, and the Dalmatæ, whose chief city was Salon, now *Salona.* The Scordisci, it would appear, were an Illyrian people, reaching as far as the river Danube. More to the south were the Dardani, who occupied the upper valleys of the river Drilo, and extended to the frontiers of Pæonia and Macedonia. The most interesting part, however, of Illyria was that which extended along the coast for nearly ninety miles, from the Gulf of Drino and the vicinity of Lissus, to the Acroceraunian Mountains and the confines of Chaonia. There we find the important towns of Epidamnus, Apollonia, Oricum, and in the interior the Atintanes, and the Dassaretii with their capital Lychnidus, situated on a great lake of the same name. Its chief rivers were the Drilo, formed by two branches, which rise nearly two hundred miles apart, and the northern branch of which is now called the *White Drino,* whilst the southern, rising in the lake Lychnitis, is called the *Black Drino;* the Apsus, now *Crevasta* or *Beratino;* the Aous, *Voioussa,* which rises in the range of Pindus, on the confines of Thessaly and Macedonia, and which separated Epirus from Illyria.

Respecting the origin of the Illyrian people we have little information on which we can depend. Their vicinity to the Thracians, and the peculiar practice of tatooing their bodies, would lead us to connect them with that important people; yet it is curious that ancient writers always distinguish them, and when they both served as light troops in the army of Alexander they formed separate bodies. Of their early history we know nothing, nor are they mentioned till the reign of Amyntas, king of Macedonia, B. C. 383, when we find Bardylis, a leader of banditti, elected king by his followers. His power increased daily, and he at last included within his kingdom all that part of Illyria which lies along the sea-coast. He attacked Macedonia, and defeating its king Amyntas, took several of its cities (Diodor. xv. 15, 19); and again, B. C. 359, we find him at war with Perdiccas, who fell in an engagement with the Illyrians (xvi. 2). The same year, however, he was defeated by Philip, the father of Alexander the Great, who succeeded on the death of Perdiccas, and was obliged to surrender all the cities and districts which he had taken from Macedonia (xvi. 4). Bardylis was succeeded by his son Clitus, who made an unsuccessful attempt to recover from Alexander that portion of Macedonia which his father had been compelled to give up (Arrian, i. 5). Clitus was succeeded by his son Pleuratus, and he again by Agron, a powerful prince, who ruled over the Dalmatians, the Greek colonies in the islands Issa, Corcyra, and Melæna, and also some of the Greek cities in Epirus. The Greeks, however, were by no means willing to be subject to one whom they considered as a barbarian, and they applied for assistance to the Romans, who were at that time beginning to interfere in the affairs of Greece. Besides, the Roman merchants had suffered considerably from the piracy of the Illyrians. The remonstrances of the Romans were little attended to, and whilst preparations were making for an effective attack, Agron died, and was succeeded in the government of Illyria by his queen Teuta. The year B. C. 229, the Romans first landed on the coast of Illyria, and before the end of the year they had so humbled the pride of the Illyrians that they were glad to sue for peace, which was granted on condition that they should give up the greater portion of the coast, and agree that no armed vessel should sail south of the Gulf of Lissus. The islands were declared free, and the country taken from the Illyrians was made over to Demetrius, whose treachery had proved the principal means of the success of the Romans. The Illyrian princes seem to have lived quietly within the bounds which the Romans had assigned them, nor do they appear to have made any attempt to recover their dominions, till the reign of Gentius, great-grandson of Agron, who was induced to join Perseus, king of Macedonia, B. C. 168, in his attack on the Romans. Thirty days were sufficient to finish the war with the Illyrians; and Gentius, with his whole family, having fallen into the hands of the conqueror, was sent to Rome to grace the prætor's triumph. From that time Illyria was considered as a Roman province, and though some portion of the country was at times rebellious, it generally submitted to the power of the Romans. (Appian, *Illyrica,* Liv. xliv.)

ILLYRIA, *Modern,* a province of the empire of Austria, which in the nomenclature of the government is classed by the name of a kingdom. When the Romans had made themselves masters of the Danube, the Save, and the Drave, they united all the country to the south of Noricum and Pannonia into a province, to which they gave the name of Illyricum. When the western Roman empire fell to pieces, and, through the pressure of the northern invaders, Byzantium was deprived of its outworks, that province lost its name, and was only distinguished by the Austrians as the Hungarian provinces to the south of the Drave.

By the peace of Presburg in 1809, these portions of country were ceded to Bonaparte, and with them also Villach, Friuli, Istria, and a part of Tyrol, to which afterwards Dalmatia was added; and they were constituted a portion of his vast empire, under the name of the Illyrian Provinces. The campaigns of 1813 and 1814, with the treaty of Vienna which followed as the consequence of these, gave back these provinces to the ancient ruler. Dalmatia, the military frontier, and the Tyrol, were detached from them; and in 1822 they were further diminished by the erection of Croatia into a separate government.

This kingdom is, for political purposes, divided into two parts, with separate chiefs; one in the north, denominated, from its capital, Laybach; and the other in the south, from the same cause called Trieste, but sometimes distinguished as the division of the sea-shore.

This kingdom extends in north latitude from 44° 59′ to 47° 8′, and in east longitude from 12° 36′ to 16° 27′. It is bounded on the north by the Austrian province of the Upper Ens, by Steyermark, and Civil Croatia; on the east by Military Croatia; on the south by the Adriatic Sea; and on the west by Venetian Lombardy and the Tyrol. The extent and population of the several districts are,—

In the North.	Extent in Square Miles.	Population in 1833.
Klagenfurth	1560	174,600
Villach	1760	131,200
Laybach	1364	166,400
Neustadt	1276	193,900
Adelsburg	1186	91,500
In the South.		
Trieste	39	58,200
Gorz	1910	171,000
Istria	2210	204,000
	11,305	1,200,800

The surface of the land is penetrated throughout with

Illyria. chains of high mountains, having some of their points very lofty, between which are valleys, some of greater, others of less extent. The sea-coast is generally flat and sandy, particularly to the westward, and abounds in morasses. The bay of Trieste on the east, and that of Quarnaro on the west, run far up into the land, and thus form the great peninsula of Istria. The valleys in the districts of Villach and Klagenfurth are stony, but have a soil of moderate fertility. In Karlstadt there is an excess of wood. The districts of Laybach, Neustadt, and Adelsburg, are full of stone quarries, marshes, and sand-hills, and are very unproductive. In the districts on the coast, the want of water is sometimes much felt. A range of mountains near Laybach divides the course of the waters, which on the north of it run to the Save and the Drave, and through them to the Black Sea; whilst those rivers in the south of the range discharge their water into the Adriatic.

The great ranges of mountains already noticed may be divided into three classes, all of which take their direction from east to west. 1*st*, The Noric Alps, which cover the northern parts of the districts of Villach and Klagenfurth. The names of the particular parts are various, but the loftiest portion is the Great Glockner, the highest points of which are 11,980 feet above the level of the sea, and are covered with snow during the whole year. From it a projection extends to the south, and separates Klagenfurth from the province of Steyermark. 2*d*, The Carinthian Alps. This range is divided into two branches, one of which extends to Steyermark, and the other terminates with the massive Terklow, from which a lower branch is continued to the river Save. 3*d*, The Julian Alps. These begin with the Terklow, which is 6500 feet in height, and run quite to the Adriatic Sea. It is a characteristic of these Julian mountains, that they are all of calcareous formation, and are filled with an incredible number of caverns and grottos. From Isonzo to the frontier of Bosnia more than a thousand of these are remarked; and it has been supposed that the whole of the mountains in question are filled with such natural excavations. Many small streams flow under as well as upon the earth; they are visible for a short space, and then bury themselves in the bowels of the earth. The washing of such streams causes a sinking of the land in many parts in the form of a funnel, which has a very remarkable appearance. The whole district, but especially the eastern part, from the peculiar formation, the numerous caverns, the subterranean rivers, the lakes, cascades, and other curiosities, presents many natural phenomena, such as are unknown in any other part of Europe.

The population consists of several original tribes, mostly of the Sclavonian race. The original language is still retained, but with a great variety of dialects, by which they may still be traced up to the countries whence they emigrated twelve or thirteen centuries ago. They adhere to their ancient customs, dress, food, and amusements, and rarely intermarry with any of the families of German origin. They are mostly occupied in agriculture, though some are employed in the mines, and a few in the towns and cities in the several kinds of labour. Their number exceeds 800,000 persons. The next are the Germans, some cultivators, others mechanics or traders, who are stated to be rather more than 300,000. Besides, there are about 60,000 Italians, residing chiefly on the Adriatic shores. The far greater proportion adhere to the Roman Catholic communion, and are zealously, or rather bigotedly, attached to it. They are under the ecclesiastical direction of thirteen bishops in the different cities. In the circles of Villach and Klagenfurth there are about 18,000 Lutherans, who have sixteen churches and eighteen chapels. Besides these, there are 200 Protestants reformed, 1200 Jews, and 1000 of the Greek church, all of whom have the free exercise of their several religious rites.

From the nature of the surface, agriculture can be but little productive, though it is well managed in the valleys about Villach and Klagenfurth. The corn produced is, according to Blumenbach, a million quarters of the four principal kinds; and in one year, where actual returns were made, the following products were harvested, viz. wheat 94,300 quarters, rye 185,000, barley 142,500, and oats 350,000 quarters. Though some maize, buck-wheat, and millet are raised, and though potatoes have been introduced and extended in every year, there is a deficiency to be supplied from other districts, which is paid for by the timber and wood-ware which is floated down by the rivers, and the preparation of which furnishes a great portion of the employment of labourers. Flax and hemp are cultivated; and there are in most parts abundance of fruit trees, and in the southern part great plenty of almonds, chestnuts, and walnuts. Some olives grow near Trieste; and about forty eimers, of thirty gallons each, are annually exported. The stock of cattle is small when compared with either the extent of the land or the number of the inhabitants. The northern districts yield no wine; in the south there is abundance, but most of it is of bad quality, and cannot be kept longer than a year.

The fishery gives considerable employment to the residents on the sea-shore, especially the taking of the large tunny and small sardinias, operations which are carried on by joint-stock companies. Many oysters also are taken, and the city of Vienna is supplied with them by a very expensive land-carriage.

The mining operations are very numerous, if not very extensive. The chief mines of lead are near Villach, Adelsburg has the most productive mines of quicksilver, and most of the other districts yield silver, iron, copper, antimony, sal-ammoniac, alum, or vitriol. The iron is chiefly converted into tools or utensils, particularly nails, which are exported. There is abundance of fossil coal in many parts, and some saline springs. The latter do not yield sufficient culinary salt for the consumption, and much is made by the sun on the sea-shore. Whatever shipping trade exists is conducted through the ports of Trieste or Fiume. As there are good roads in all directions, the internal trade with the other dominions of Austria is very extensive, and rapidly increasing.

The courts of law, both civil and criminal, are held at Klagenfurth, which is also the chief seat of the police, and of the treasury board for the whole kingdom.

ILLYRIUS, Mathias, Flaccus, or Francowitz, one of the most learned divines of the Augsburg confession, born in Istria, anciently called Illyria, in 1520. He is said to have been a man of considerable genius, extensive learning, and of great zeal against popery; but he was of a restless and passionate temper, which overbalanced all his good qualities, and occasioned much disturbance in the Protestant church. He published a great number of books, and died in 1575.

ILMINSTER, a town of the county of Somerset, in the hundred of Abdick, 135 miles from London. It stands in a fertile district, and has a market, which is held on Saturday. There was formerly a considerable manufacture of woollens, but it has declined, and of late years has been in some measure replaced by mills for making lace net. There is a large church, formerly conventual, and an excellently endowed grammar-school. The population amounted in 1801 to 2045, in 1811 to 2160, in 1821 to 2156, and in 1831 to 2957.

IMAGE, in a religious sense, is an artificial representation or similitude of some person or thing, used either by way of decoration and ornament, or as an object of religious worship and adoration. In the last sense it is used indifferently with the word idol.

The noble Romans preserved with great care the images of their ancestors, which were commonly made of wax or wood, though sometimes of marble or brass, and had them carried in procession at their funerals and triumphs. They placed these images in the vestibules of their houses, where they remained, even if the houses happened to be sold, it being accounted impious to displace them. It was not, however, permitted to all who had the images of their ancestors in their houses, to have them carried at their funerals. This was a distinction granted to such alone as had honourably discharged their offices; for those who failed in this respect forfeited their privilege, and in case they had been guilty of any great crime, their images were broken in pieces.

The Jews absolutely condemned all images, and did not suffer any statues or figures to be placed in their houses, much less in their synagogues or places of worship.

The use and adoration of images are subjects which have long been controverted in the world. It appears, from the practice of the primitive church, recorded by the earlier fathers, that Christians, during the first three centuries after Christ, and the greater part of the fourth, neither worshipped images nor used them in worship. However, the greater part of the Roman Catholic divines maintain that the use and worship of images are as ancient as the Christian religion itself; and to prove this, they allege a decree, said to have been made in a council held by the apostles at Antioch, commanding the faithful, that they might not err about the object of their worship, to make images of Christ, and worship them. (Baron. *ad Ann.* 102.) But no notice is taken of this decree till seven hundred years after the apostolic times, when the dispute about images had commenced. The first instance which occurs in any credible author, of images amongst Christians, is that recorded by Tertullian (*De Pudicitia*, c. 10), of certain cups or chalices, as Bellarmine pretends, on which was represented the parable of the good shepherd carrying the lost sheep on his shoulders. But this instance only proves that the church at that time did not think emblematical figures unlawful ornaments of cups or chalices. Another instance is taken from Eusebius (*Hist. Eccl.* lib. vii. cap. 18), who says, that in his time there were to be seen two brass statues in the city of Paneas or Cæsarea Philippi; the one of a woman on her knees, with her arms stretched out; the other of a man over against her, with his hand extended to receive her. These statues were said to be the images of our Saviour and of the woman whom he cured of an issue of blood. From the foot of the statue representing our Saviour, says the historian, sprung up an exotic plant, which, as soon as it grew to touch the border of his garment, was said to cure all sorts of distempers. Eusebius, however, vouches for none of these things; nay, he supposes that the woman who erected this statue of our Saviour was a pagan, and ascribes it to a pagan custom. The primitive Christians abstained from the worship of images, not, as the Romanists pretend, from tenderness to heathen idolators, but because they thought it unlawful in itself to make any images of the Deity. (Justin Mart. *Apol.* ii. p. 44; Clem. Alex. *Strom.* 5, *Strom.* 1, and *Protr.* p. 46; Aug. *de Civit. Dei*, lib. vii. c. 5, and lib. iv. c. 32; Id. *de Fide et Symb.* c. 7; Lactant. lib. ii. c. 3; Tertull. *Apol.* c. 12; Arnob. lib. vi. p. 202.) Some of the fathers, as Tertullian, Clemens Alexandrinus, and Origen, were of opinion that, by the second commandment, the arts of painting and engraving were rendered unlawful to a Christian. The custom of admitting pictures of saints and martyrs into the churches was rare in the latter end of the fourth century; but it became common in the fifth, and in the following century the custom of thus adorning churches became almost universal, both in the east and the west.

The Lutherans censure the Calvinists for breaking the images in the churches of the Catholics, looking on it as a kind of sacrilege; and yet they condemn the Romanists as idolators.

The Mahommedans have a perfect aversion to images, which has led them to destroy most of the beautiful monuments of antiquity, both sacred and profane, at Constantinople.

IMAGE, in *Rhetoric*, signifies a lively representation of any thing in discourse. Images, in discourse, are, according to Longinus, any thoughts proper to produce expressions, which present a kind of picture to the mind. But, in the more limited sense, images are such expressions as fall from us when, by a kind of enthusiasm, or an extraordinary emotion of the soul, we seem to see the things of which we speak, and present them before the eyes of those who hear us.

IMAGE, in *Optics*, a figure in the form of any object, made by the rays of light issuing from the several points of it, and meeting in so many other points, either at the bottom of the eye, or on any other ground, or on any transparent medium, where there is no surface to reflect them. Thus we are said to see all objects by means of their images formed in the eye.

IMAGINARY QUANTITIES, or *Impossible Quantities*, in *Algebra*, are the even roots of negative quantities; which expressions are imaginary, or impossible, or opposed to real quantities; as $\sqrt{-aa}$, or $\sqrt[4]{-a^4}$. For as every even power of any quantity whatever, whether positive or negative, is necessarily positive, or has the sign $+$, because $+$ by $+$, or $-$ by $-$, give equally $+$; hence it follows that every even power, as the square, for instance, which is negative, or having the sign $-$, has no possible root; and therefore the even roots of such powers or quantities are said to be impossible or imaginary. The mixed expressions arising from imaginary quantities joined to real ones, are also imaginary; as $a - \sqrt{-aa}$, or $b + \sqrt{-aa}$.

IMAGINARY Roots of an equation are those roots or values of the unknown quantity which contain some imaginary quantity. Thus the roots of the equation $xx + aa = 0$, are the two imaginary quantities $+\sqrt{-aa}$ and $-\sqrt{-aa}$, or $+a\sqrt{-1}$ and $-a\sqrt{-1}$.

IMAGINATION, a power or faculty of the mind, by which it conceives and forms ideas of things communicated to it by means of the organs of sense.

Force of IMAGINATION. See APPARITIONS.

IMAGO, in *Natural History*, is a name given by Linnæus to the third state of insects, when they appear in their proper shape and colours, and undergo no further transformation.

IMAM, IMAUM, or IMAN, a minister in the Mahommedan church, answering to a parish priest amongst us. The word properly signifies what we call a prelate, *antistes*, one who presides over others; but the Moslemins frequently apply it to a person who has the care and intendency of a mosque, and reads prayers to the people, which they repeat after him.

IMAM is also applied, by way of excellence, to the four chiefs or founders of the four principal sects in the Mahommedan religion. Thus Ali is the imam of the Persians; Abu-beker the imam of the Soonites, which is the sect followed by the Turks; and Saphii, or Safi-y, the imam of another sect.

IMAUS, in *Ancient Geography*, the largest mountain of Asia, and part of Taurus, from which the whole of India runs off into a vast plain, resembling Egypt. It extends through Scythia, as far as to the *Mare Glaciale*, dividing it into *Scythia intra Imaum*, and *Scythia extra Imaum;* and also stretching out along the north of India to the Eastern Ocean, separates it from Scythia.

IMBECILITY, a languid, infirm state of the body, which being greatly impaired, is unable to perform its usual exercises and functions.

IMBIBING, the action of a dry porous body, which absorbs a moist or fluid one.

IMBRICATED, a term used by some botanists to express the figure of the leaves of some plants, which are hollowed like an *imbrex*, or gutter-tile, or are laid in close series over one another like the tiles of a house.

IMBRO, or IMRUS, an island in the Archipelago, to the south-west of the Gulf of Saros, eighty-six square miles in extent. It has 4000 Greek inhabitants, who produce corn, wine, oil, and cotton wool, and occupy one town and several villages. Long. 25. 40. E. Lat. 40. 10. N.

IMITATION, derived from the Latin *imitare*, to represent or repeat a sound or action, either exactly or nearly in the same manner as they were originally exhibited.

IMITATION, in *Music*, admits of two different senses. Sound and motion are either capable of imitating themselves by a repetition of their own particular modes, or of imitating other objects of a nobler and more abstracted nature. Nothing perhaps is so purely mental, nothing so remote from external sense, as not to be imitable by music. Dramatic or theatrical music contributes to imitation no less than painting or poetry; it is on this common principle that we must investigate both the origin and the final cause of all the fine arts. But this imitation is not equally extensive in all the imitative arts. Whatever the imagination can represent to itself is in the department of poetry. Painting, which does not present its pictures to the imagination immediately, but to external sense, and to one sense alone, paints only such objects as are discoverable by sight. Music might appear subjected to the same limits with respect to the ear; yet it is capable of painting every thing, even such images as are objects of ocular perception alone. By a magic almost inconceivable, it seems to transform the ears into eyes, and endow them with the double function of perceiving visible objects; and it is the greatest miracle of an art, which can only act by motion, that it can make that very motion represent absolute quiescence. Imitation, in its technical sense, is a reiteration of the same air, or of one which is similar, in several parts where it is repeated by one after the other, either in unison, or at the distance of a fourth, a fifth, a third, or any other interval whatever.

IMITATION, in *Oratory*, is an endeavour to resemble a speaker or writer in those qualities regarding which we propose them to ourselves as patterns. The first historians amongst the Romans were, according to Cicero, very dry and jejune, till they began to imitate the Greeks, and then they became their rivals. It is well known how closely Virgil has imitated Homer in his Æneid, Hesiod in his Georgics, and Theocritus in his Eclogues. Terence copied from Menander, and Plautus from Epicarmus, as we learn from Horace (lib. ii. *Ep. ad August.*), who himself owes many of his beauties to the Greek lyric poets. Cicero appears, from many passages in his writings, to have imitated the Greek orators. Thus Quintilian said of him, that he expressed the strength and sublimity of Demosthenes, the copiousness of Plato, and the delicacy of Isocrates.

IMMERSION, that act by which a thing is plunged into water or any other fluid.

IMMERSION, in *Astronomy*, is when a star or planet is so near the sun, with regard to our observations, that we cannot see it; being, as it were, enveloped and hid in the rays of that luminary. It also denotes the beginning of an eclipse of the moon, or that moment when the moon begins to be darkened, and to enter into the shadow of the earth.

IMMERITIA, or IMIRETTA, or, as it is sometimes called, Iberia, a country of Asia, to the north of Persia, bounded on the east by Georgia, and on the south by the Mossain Hills; on the north it extends as far as the principal chain of the Caucasus, and on the west the Euxine and the Hippus are the frontier lines. It lies between the 43d and 44th degrees of north latitude. It is in general of a rich soil, but is greatly depopulated and neglected; the few inhabitants in the country being as little inclined to industry as the other inhabitants of the Caucasus. In 1784 it acknowledged the supremacy of Russia, but it is in a great measure independent in its internal government. The manners of the natives are rude and simple. They generally inhabit some secluded spot in woody hills or in pleasant valleys; and here, in contented solitude, the native of Immeritia avoids the incursions of his enemies in his secret retreat. They have a method, however, of calling each other together on important occasions, by means of deep-sounding tones; and on this signal being given, hundreds of people issue from places where no one could have supposed there had been a single creature. They are chiefly of Georgian origin. The principal town is Cotatis, situated on the left bank of the Phasis river; an inconsiderable place, inhabited by about eighty Jewish, Armenian, and Turkish families. The Quirilia is the only river of consequence in Immeritia. It takes its rise in the Soani ridges, and being greatly increased by the snow-streams which descend from the Georgian side of the Caucasus, enters the Phasis in the neighbourhood of Cotatis.

IMMOLATION, a ceremony used in the Roman sacrifices. It consisted in throwing upon the head of the victim some sort of corn and frankincense, together with the *mola* or salt cake, and a little wine.

IMMORTAL, that which will last to all eternity, as having in it no principle of alteration or corruption.

IMMUNITY, a privilege or exemption from some office, duty, or imposition. Immunity is more particularly understood of the liberties granted to cities and communities.

IMMUTABILITY, the condition of a thing that cannot change. Immutability is one of the divine attributes.

IMOLA, a city of Italy, of the province of Ravenna, in the papal dominions. It is situated on an island formed by two branches of the river Santerno, in a fruitful valley, surrounded by poplars, with vines entwined amongst the branches. It is the see of a bishop, and has a cathedral, fifteen churches, seventeen religious houses for the two sexes, and 8350 inhabitants, chiefly employed in producing wine. Long. 11. 30. 10. E. Lat. 44. 21. 32. N.

IMPANNELLING, in *Law*, signifies the writing down or entering into a parchment, list, or schedule, the names of a jury summoned by the sheriff to appear for such public services as juries are employed in.

IMPARLANCE, in *English Law*, a petition in court for a day, to consider or advise what answer the defendant shall make to the plaintiff's action; and hence it is the continuance of the cause till another day, or a longer time given by the court.

IMPEACHMENT, an accusation and prosecution for treason and other high crimes and misdemeanours. Any member of the lower house of parliament may impeach any one belonging either to that body or to the House of Lords. The method of proceeding is to exhibit articles on behalf of the Commons, by whom managers are appointed to make good their charge. These articles are carried to the Lords, by whom every person impeached by the Commons is always tried; and if they find him guilty, no pardon under the great seal can be pleaded to such an impeachment. 12 Will. III. cap. ii.

IMPECCABILES, in *Ecclesiastical History*, a name given to those heretics who boasted that they were impeccable, and that there was no need of repentance.

IMPECCABILITY, the state of a person who cannot sin, or a grace, privilege, or principle, which puts him out of the possibility of sinning.

The schoolmen distinguish several kinds and degrees of impeccability; that of God belongs to him by nature; that of Jesus Christ, considered as man, belongs to him by the hypostatical union; that of the blessed is a consequence of their condition; and that of men is the effect of a confirmation in grace, and is rather called *impeccance* than *impeccability*. Accordingly, divines distinguish between these two; and this distinction is found necessary in the disputes against the Pelagians, in order to explain certain terms in the Greek and Latin fathers, which without this distinction would be easily confounded.

IMPEDIMENTS, in *Law*, are such hindrances as put a stop or stay to a person's seeking his right by due course of law. Persons under impediments are those under age or coverture, *non compos mentis*, in prison, beyond sea, and the like, who, by a saving in our laws, have time to claim and prosecute their rights, after the impediments are removed.

IMPENETRABILITY, in *Philosophy*, that property of body by which it cannot be pierced by another. Thus a body which so fills a space as to exclude all others, is said to be impenetrable.

IMPERFECT, something that is defective, or which wants some of the properties found in other beings of the same kind.

Imperfect Number is that the aliquot parts of which, taken all together, do not make a sum that is equal to the number itself, but either exceed it or fall short of it; being an abundant number in the former case, and a defective number in the latter. Thus 12 is an abundant imperfect number, because the sum of all its aliquot parts, 1, 2, 3, 4, 6, makes 16, which exceeds the number 12. And 10 is a defective imperfect number, because its aliquot parts 1, 2, 5, taken all together, make only 8, which is less than the number 10 itself.

IMPERIAL, something belonging to an emperor, or empire. See Emperor, and Empire.

Imperial Cities, in Germany, were those which owned no other head but the emperor. These were a kind of little commonwealths, the chief magistrates of which did homage to the emperor; but in other respects, and in the administration of justice, they are sovereign. There were formerly a great many such cities; but since 1815 there are only four, Hamburg, Bremen, Lubec, and Frankfort.

Imperial Diet, is an assembly or convention of all the states of the empire. See Germany, and Diet.

IMPETRATION, the act of obtaining any thing by request or prayer. Imperation was more particularly used in our statutes for the pre-obtaining from the court of Rome of benefices and church-offices in England, which were at the disposal of the king and other lay patrons of the realm; the penalty of which is the same with that of provisors. 25 Edw. III.

IMPOSITION of Hands, an ecclesiastical action, by which a bishop lays his hand on the head of a person, in ordination, confirmation, or in benediction. This practice is also observed by the dissenters at the ordination of their ministers, when all the ministers present place their hands on the head of him whom they are ordaining, whilst one of them prays for a blessing on him and his future labours. This they retain as an ancient practice, justified by the example of the apostles, when no extraordinary gifts are conveyed. However, they are not all agreed as to the propriety of this ceremony, nor do they consider it as an essential part of ordination.

Imposition of hands was a Jewish ceremony, introduced not by any divine authority, but by custom; it having been the practice amongst that people, whenever they prayed to God for any person, to lay their hands on his head. Our Saviour observed the same custom, both when he conferred his blessing on children, and when he cured the sick. The apostles likewise laid hands on those upon whom they bestowed the Holy Ghost. The priests observed the same custom when any one was received into their body; and the apostles themselves underwent the imposition of hands afresh every time they entered upon any new design.

IMPOSSIBLE, that which is not possible, or which cannot be done or effected. A proposition is said to be impossible when it contains two ideas which mutually destroy each other, and which can neither be conceived nor united together. Thus it is impossible that a circle should be a square; because we conceive clearly that squareness and roundness destroy each other by the contrariety of their figure.

There are two kinds of impossibilities, physical and moral. Physical impossibility is that which is contrary to the law of nature. A thing is morally impossible, when of its own nature it is possible, but yet is attended with such difficulties that, all things considered, it appears impossible. Thus it is morally impossible that all men should be virtuous; or that a man should throw the same number with three dice a hundred times successively.

A thing which is impossible in law is the same with a thing impossible in nature; and if any thing in a bond or deed be impossible to be done, such deed or bond is void. 21 Car. I.

IMPOTENCE, or Impotency, in general, denotes want of strength, power, or means, to perform any thing.

Divines and philosophers distinguish two sorts of impotency, natural and moral. The first is a want of some physical principle, necessary to an action, or where a being is absolutely defective, or not free and at liberty to act; the second only imports a great difficulty, as a strong habit to the contrary, a violent passion, or the like.

Impotency is a term more particularly used to signify a natural inability for coition. Impotence with respect to men is the same as sterility in women There are many causes of impotence, as, a natural defect in the organs of generation, which seldom admits of a cure, and accidents or diseases; in which cases impotence may or may not be remedied, according as these are curable or otherwise. On this subject some curious and original observations by Mr John Hunter may be found in his Treatise on the Venereal Disease. He considers impotency as depending upon two causes, one of which he refers to the mind, and the other to the organs.

Impotency is a canonical disability, to avoid marriage in the spiritual court. The marriage is not void *ab initio*, but voidable only by sentence of separation during the life of the parties.

IMPRECATION (derived from *in*, and *precor*, I pray), a curse or wish that some evil may befall any one.

The ancients had their goddesses, called in Latin *Diræ*, that is, *Deorum iræ*, who were supposed to be the executioners of evil consciences. They were called *Diræ* in heaven, *Furies* on earth, and *Eumenides* in hell. The Romans owned but three of these, and the Greeks only two. They invoked them with prayers and pieces of verses to destroy their enemies.

IMPRESSING Seamen. The power of impressing seafaring men for the naval service, by the king's commission, has been a matter of much dispute, and submitted to with great reluctance; though Sir Michael Forster strenuously contends that the practice of impressing, and granting powers to the admiralty for that purpose, is of a very ancient date, and has been uniformly continued by a regular series of precedents to the present time, from which he concludes that it is part of the common law. The difficulty arises from this, that no statute has expressly declared this power to be in the crown, though many of them very strongly imply it. But whatever may be said as to the legality of this method of manning the navy, there can be no doubt that it is a gross invasion of natural liberty; and hence it has in recent times been very generally reprobated, not only as forming a great anomaly in a free country, where natural rights are in all other cases respected, but likewise as contrary to sound policy, and at variance with the principles on which recruitment ought to be conducted, excepting in those cases of imperious necessity which imply the suspension of all ordinary rights and laws.

IMPRESSION is applied to the species of objects which are supposed to make some mark or impression on the senses, the mind, and the memory. The peripatetics assert, that bodies emit species resembling them, which are conveyed to the common *sensorium*, and there rendered intelligible by the active intellect; and, when thus spiritualized, they are called *expressions*, or *express species*, as being expressed from the others.

Impression also denotes the *edition* of a book, meaning thereby the mechanical part only; whereas *edition*, besides this, includes the care of the editor, who corrected or augmented the copy, adding notes and illustrations to render the work more useful.

IMPRISONMENT, the state of a person restrained of his liberty, and detained under the custody of another.

No person is to be imprisoned but as the law directs, either by the command or order of a court of record, or by lawful warrant; or the king's process, on which one may be lawfully detained. Where the law gives power to imprison, in such case it is justifiable, provided he who does it in pursuance of a statute exactly pursues the statute in the manner of doing it; for otherwise it will be deemed false imprisonment, and consequently it is unjustifiable.

False Imprisonment. Every confinement of the person is an imprisonment, whether it be in a common prison, or in a private house, or in the stocks, or even by forcibly detaining one in the public streets. Unlawful or false imprisonment consists in such confinement or detention without sufficient authority. False imprisonment also may arise by executing a lawful warrant or process at an unlawful time, as on a Sunday; or in a place privileged from arrests, as in the verge of the king's court. This is the injury. The remedy is of two sorts; the one *removing* the injury, the other *making satisfaction* for it.

IMPROMPTU, or *Inpromptu*, a Latin word employed to signify a piece made off-hand, or *extempore*, without any previous meditation, by mere force and vivacity of imagination.

IMPROBATION, in *Scotch Law*, the name of any action brought for setting aside any deed or writing upon the head of forgery.

IMPULSION, in *Mechanical Philosophy*, a term employed to express a supposed peculiar exertion of the powers of body, by which a moving body changes the motion of another body by hitting or striking it. The plainest case of this action is when a body in motion strikes another body at rest, and puts it in motion by the stroke. The body thus put in motion is said to be *impelled* by the other; and this method of producing motion is called *impulsion*, to distinguish it from *pression*, *thrusting*, or *protrusion*.

IMPURITY, in the law of Moses, is any legal defilement. Of this there were several sorts. Some were voluntary, as the touching a dead body, or any animal that had died of itself, or any creature that was esteemed unclean; or the touching things holy by one who was not clean, or was not a priest; the touching one who had a leprosy, or who was polluted by a dead carcass, and so on. Sometimes these impurities were involuntary, as when any one inadvertently touched bones, or a sepulchre, or any thing polluted; or fell into diseases which pollute, as the leprosy. The beds, clothes, and moveables, which had touched any thing unclean, contracted also a kind of impurity, and in some cases communicated it to others.

These legal pollutions were generally removed by bathing, and lasted no longer than the evening. The person polluted plunged over head in the water, and either had his clothes on when he did so, or washed himself and his clothes separately. Other pollutions continued seven days, as that which was contracted by touching a dead body. Some impurities lasted forty or fifty days, whilst others again lasted till the person was cured.

Many of these pollutions were expiated by sacrifices, and others by a certain water or ley made with the ashes of a red heifer, sacrificed upon the great day of expiation. When the leper was cured, he went to the temple and offered a sacrifice of two birds, one of which was killed, and the other set at liberty. He who had touched a dead body, or had been present at a funeral, was to be purified with the water of expiation, and this upon pain of death. The woman who had been delivered offered a turtle and a lamb for her expiation; or, if she was poor, two turtles or two young pigeons. These impurities, which the law of Moses has expressed with the greatest care and accuracy, were only figures of other more important impurities, such as the sins and iniquities committed against God, or faults committed against our neighbour. The saints and prophets of the Old Testament were sensible of this; and our Saviour, in the gospel, has strongly inculcated that they are not outward and corporeal pollutions which render us unacceptable to God, but such inward pollutions as infect the soul, and are violations of justice, truth, and charity.

IMPUTATION, in general, the charging something to the account of one which belonged to another. Thus, the assertors of original sin maintain that Adam's sin is imputed to all his posterity; and, in the same sense, the righteousness and merits of Christ are imputed to true believers.

INACCESSIBLE, something that cannot be approached by reason of intervening obstacles.

INALIENABLE, that which cannot be legally alienated, or made over to another. Thus the dominions of the king, the revenues of the church, the estates of a minor, and the like, are inalienable, otherwise than with a reserve of the right of redemption.

INANIMATE, a body that has either lost its vitality, or that is not of a nature capable of having any.

INANITION, amongst physicians, denotes the state of the stomach when empty, in opposition to repletion.

INANITY, the scholastic term for emptiness or absolute vacuity, and implying the absence of all body or matter whatsoever, so that nothing remains but mere space.

INAUGURATION, the coronation of an emperor or king, or the consecration of a prelate; and so called from the ceremonies used by the Romans when they were received into the college of augurs.

INCA, or Ynca, a name given by the natives of Peru to their kings and princes of the blood. Pedro de Cieca, in his Chronicles of Peru, speaking of the origin of the Incas, states that that country was, for a long time, the theatre of all manner of crimes, of war, dissension, and the most dreadful disorders, till at last two brothers appeared, one of whom, called Mangocapa, having built the city of Cusco, made laws, and established order and harmony by his wise regulations, took the name of Inca, which signifies king or great lord; and this name descended to his posterity.

INCAMERATION, a term used in the chancery of Rome, for the uniting of lands, revenues, or other rights, to the pope's domains.

INCANTATION denotes certain ceremonies, accompanied with a formula of words, supposed to be capable of raising devils, spirits, &c.

INCAPACITY, in the canon law, is of two kinds; first, the want of a dispensation for age in a minor, and for legitimation in a bastard, &c., which renders the provision of a benefice void in its original; and, secondly, crimes and heinous offences, which annul provisions at first valid.

INCARNATION, in *Theology*, signifies the act by which the Son of God assumed the human nature, or the mystery by which Jesus Christ, the Eternal Word, was made Man, in order to accomplish the work of our salvation.

Incarnation (formed from *in*, and *caro*, flesh), in *Surgery*, signifies the healing and filling up of ulcers and wounds with new flesh. See Surgery.

INCARNATIVES, in *Surgery*, medicines which were supposed to assist nature in filling up wounds or ulcers with new flesh.

INCENDIARY, in *Law*, is applied to one who is guilty of maliciously setting fire to another's dwelling-house or premises. A bare intent or attempt to do this, by actually setting fire to a house, unless it absolutely burns, does not fall within the description of *incendit et combussit.* But the burning and consuming of any part is sufficient, though the fire be afterwards extinguished. It must also be a malicious burning, otherwise it is only a trespass. This offence is called arson in the English, and wilful fire-raising in the Scotch law.

Amongst the ancients, criminals of this kind were adjudged to be burned. *Qui œdes, acervumque frumenti juxta domum positum sciens, prudensque dolo malo combusserit, vinctus igni necatur.* The punishment of arson was death by the ancient Saxon laws and by the Gothic constitutions; and in the reign of Edward I. incendiaries were burned to death. The statute 8 Henry VI. c. 6, made the wilful burning of houses, under special circumstances, high treason; but it was reduced to felony by the general acts of Edward VI. and Queen Mary. This offence was denied the benefit of clergy by 21 Henry VIII. c. 1, which statute was repealed by 1 Edward VI. c. 12; and arson was held to be ousted of clergy with respect to the principal, by inference from the statute 4 and 5 Philip and Mary, c. 4, which expressly denied it to the accessory; though now it is expressly denied to the principal also by 9 Geo. I. c. 22.

INCENSE, or Frankincense, in the *Materia Medica*, a dry resinous substance, known amongst authors by the names *tus* and *olibanum.*

Incense is a perfume with which the Pagans and the Roman Catholics still perfume their temples and altars. The word comes from the Latin *incensum*, that is, *burned*, by taking the effect for the thing itself.

The burning of incense formed part of the daily service of the ancient Jewish church. The priests having drawn lots to ascertain who should offer it, the person destined took a large silver dish, in which was a censer full of incense; and being accompanied by another priest carrying some live coals from the altar, went into the temple, where, in order to give notice to the people, they struck upon an instrument of brass placed between the temple and the altar; and being returned to the altar, he who brought the fire left it there, and went away. Then the offerer of incense having said a prayer or two, waited the signal, which was the burning of the holocaust; immediately after which he set fire to the incense, the multitude continuing all the time in prayer.

INCEPTIVE, a word used by Dr Wallis to express such moments, or first principles, as, though of no magnitude themselves, are yet capable of producing results which are. Thus a point has no magnitude itself, but is inceptive of a line which it produces by its motion. So a line, though it have no breadth, is yet inceptive of breadth; that is, it is capable, by its motion, of producing a surface which has breadth.

INCEST, the crime of illicit commerce between persons who are related in a degree in which marriage is prohibited by the laws of the country. Most nations look on incest with horror.

Incest, Spiritual, a crime committed in like manner between persons who have a spiritual alliance by means of baptism or confirmation.

Spiritual incest is also understood of a vicar, or other beneficiary, who holds two benefices, the one of which depends upon the collation of the other. Such a spiritual incest renders both of these benefices vacant.

INCH, a well-known measure of length, being the twelfth part of a foot, and equal to three barleycorns in length.

Inch (contracted from the Gaelic *innis*, an island), a word prefixed to the names of different places in Scotland and Ireland.

Inch-Colm, or *Columba*, the isle of Columba, an island situated in the Frith of Forth in Scotland, and famous for its monastery. See Forth.

This monastery was founded about 1123, by Alexander I. In passing the Frith of Forth he was overtaken by a violent storm, which drove him to this island, where he met with the most hospitable reception from a poor hermit, then residing in the chapel of St Columba, and who, for the three days during which the king remained there tempest-bound, entertained him with the milk of his cow and a few shell-fish. His majesty, from the sense of the danger which he had escaped, and in gratitude to the saint to whom he attributed his safety, vowed some token of respect, and accordingly founded here a monastery of Augustines, and dedicated it to St Columba. Allan de Mortimer, lord of Aberdour, who attended Edward III. in his Scotch expedition, bestowed half of those lands on the monks of this island, for the privilege of a family burial-place in their church. The buildings erected in consequence of the piety of Alexander were considerable; and there is still to be seen a large square tower belonging to the church, with the ruins of the church, and of several other buildings. The wealth of this place in the time of Edward III. proved so strong a temptation to his fleet, then lying in the Forth, as to suppress all the horror of sacrilege and respect to the sanctity of the inhabitants. The English landed, and spared not even the furniture more immediately consecrated to divine worship. But due vengeance overtook them; for, in a storm which instantly followed, many of them perished; and those who escaped, struck with the justice of the judgment, vowed to make ample recompense to the injured saint. The tempest ceased, and they performed the promised atonement.

Inch-Keith, a small island situated in the same frith, about midway between the port of Leith and Kinghorn on the opposite shore. See Forth.

This island is said to derive its name from the gallant Keith, who so greatly signalized himself by his valour in 1010, in the battle of Barry, in Angus, against the Danes; after which he received in reward the barony of Keith, in Lothian, and this little island. In 1549 the English fleet, sent by Edward VI. to assist the lords of the congregation against the queen-dowager, landed, and began to fortify this island, the importance of which they became sensible of, after their neglect of securing the port of Leith, so lately in their power. They left here five companies to cover the workmen, under the command of Cotterel; but their operations were soon interrupted by M. Desse, general of the French auxiliaries, who took the place, after a gallant defence on the part of the English. The Scotch kept possession of the island for some years;

but at last the fortifications were destroyed by act of parliament, to prevent it from being of any use to the former. The French gave it the name of *L'Isle des Chevaux*, from its property of fattening horses. A light-house, which has proved highly beneficial to the shipping frequenting the Forth, was erected on the island in 1805.

Inch-Garvie, a small island, also lying in the Frith of Forth, near Queensferry. See Forth.

INCHOATIVE, a term signifying the beginning of a thing or action, and the same with what is otherwise called inceptive.

Inchoative Verbs denote, according to Priscian and other grammarians, verbs which are characterised by the termination *sco* or *scor* added to their primitives; as *augesco* from *augeo*, *calesco* from *caleo*, *irascor* from *ira*, and so of the rest.

INCIDENCE denotes the direction in which one body strikes on another. See Optics and Mechanics.

INCIDENT, in *Law*, is a thing appertaining to or following another which is principal. A court baron is inseparably incident to a manor, and a court of pie-powders to a fair.

Incident Diligence, in *Scotch Law*, a warrant granted by a lord ordinary in the Court of Session, for citing witnesses for proving any point, or for production of any writing necessary for preparing the cause for a final determination, or before it goes to a general proof.

INCINERATION (derived from *in*, and *cinis*, ashes), in *Chemistry*, the reduction of any substance into ashes by burning.

INCISIVE, an appellation applied to whatever cuts or divides. Thus the fore teeth are called *dentes incisivi*, or cutters; and medicines of an attenuating nature, incidents, or incisive medicines.

INCLE, a kind of tape made of linen yarn.

INCLINATION, a term used by mathematicians, and signifying the mutual approach, tendency, or leaning of two lines or two planes towards each other, so as to form an angle.

INCLINED Plain, in *Mechanics*, one which forms an oblique angle with the horizon.

INCOGNITO is applied to a person who is in any place where he would not be known; but more particularly to princes or great men who enter towns or walk the streets without their ordinary train, or the usual marks of their distinction and quality.

INCOMBUSTIBLE Cloth. See Mineralogy. On this Cronstedt observes, that the natural store of the asbesti is in proportion to their economical use, both being very inconsiderable. "It is an old tradition," says he, "that in former ages they made cloths of the fibrous asbesti, which is said to be composed of the word *byssus*; but it is not probable, since, if one may conclude from some trifles now made of it, as bags, ribbons, and other things, such a dress could neither have an agreeable appearance, nor be of any conveniency or advantage. It is more probable that the Scythians dressed their dead bodies which were to be burned, in a cloth manufactured of this stone; and this perhaps has occasioned the above fable." M. Magellan confirms this opinion of Cronstedt's, and informs us that some of the Romans also enclosed dead bodies in cloth of this kind.

Incombustible, something that cannot be burned or consumed by fire. See Asbestos.

INCOMMENSURABLE, in *Geometry*, is a term applied to homogeneous magnitudes which have no common measure, or whereof one cannot be denoted as either multiple, aliquot part, or aliquot parts, of the other, or whose ratio cannot be represented by numbers.

The great Στοιχειωτης of the ancients has not expressly called attention to this negative relation of magnitudes earlier than in the tenth book of his *Elements*; but he has kept it steadily in view in the preceding parts of the work. Hence he has two distinct treatises of proportion; the one of proportion in *magnitudes*, the other of proportion in *numbers*.

In the second proposition of the tenth book it is shown, that if from the greater of two magnitudes we take the less, or the highest multiple of the less which it contains, then take from the less the remainder, or the highest multiple of the remainder which is contained in it, and so on continually; whenever this process becomes interminable, the magnitudes have no common measure.

The simplest instance of this interminable process to which we can refer, is in the case of a straight line and the greater segment of the same divided in extreme and mean ratio. For, by proposition 5, book xiii. it appears, that when the greater segment is taken from the whole, the remainder (that is, the less segment) has exactly the same relation to this greater segment which the greater has to the whole, and so on for ever.

If we begin a similar process with the diagonal and side of a square, at the end of every two operations the two lines with which we have to proceed have the same *relative* magnitude as the two with which we began; and thus we should never come to an end. If, therefore, the side of a square be one foot, we cannot possibly express the diagonal in feet or parts of a foot.

In fact, although, in ultimate practice, every quantity with which the mathematician has to deal is represented by numbers, whole or fractional, the cases where this representation is not metaphysically accurate are far more numerous than where it is perfect.

Take, for instance, the vulgar logarithms of the natural numbers. Let $\frac{p}{q}$ be the logarithm of the number N (where p, q, and the other general characters which we shall use, denote integer numbers). Then $N = 10^{\frac{p}{q}}$, whence $N^q = 10^p = 2^p \times 5^p$. And, since the q power of N contains no prime factors but 2 and 5, N itself can contain no other. Let $N = 2^r \times 5^s$. We have now $2^{qr} \times 5^{qs} = 2^p \times 5^p$; so that qr and qs being each equal to p, we have $\frac{p}{q} = r$, and $N = 10^r$. Thus $\frac{p}{q}$ is necessarily integer, consequently not one logarithm of the series can be properly a fraction; and those which are integer succeed only at intervals, of which each is ten times as great as the preceding.

We have said that the impossibility of reducing the relation of concrete magnitudes to that of numbers, in an infinity of cases, has caused Euclid to form two distinct treatises of proportion. And it is easy to see by what considerations he has passed from the simpler to the more complex, though this last has priority in the order of the *Elements*.

Two numbers are called proportional to two other, or "the first is said to have to the second the same ratio which the third has to the fourth, when the first is the same multiple (aliquot) part or parts of the second which the third is of the fourth." But we have seen that there may be *magnitudes* of the same kind, whereof one is neither multiple, part, nor parts of another; in other words, that have no common measure, no numerical ratio. Yet we may conceive two such magnitudes to be related to each other κατα πηλικοτητα, exactly like other two.

If D and S be the diagonal and side of a square; and Δ and Σ the diagonal and side of another square; and if S and Σ be divided into the same number of equal parts, however great the number and small the parts, we may conceive and easily prove, that whenever D is greater than m of the parts of S, but less than $m + 1$, Δ is also greater than m of the parts of Σ, but less than $m + 1$. So that, amongst incommensurable magnitudes, the first might be said to have the same ratio to the second which the third has to the fourth, when, "according as the first is greater or less than any multiple, part, or parts whatsoever of the second, the third is greater or less than the same multiple, part, or parts of the fourth." And both commensurable and incommensurable magnitudes might be brought under the following definition: "The first of four magnitudes has the same ratio to the second which the third has to the fourth, when, according as the first is greater than any multiple, part, or parts whatsoever of the second, equal to it, or less, the third is greater than the same multiple, part, or parts of the fourth, equal to it, or less."

Thus, if $\frac{n}{m}$B signify n of the magnitudes, of which B contains m, we might say, A has the same ratio to B which C has to D, if, according as A is greater than $\frac{n}{m}$B, equal to it, or less, C is greater than $\frac{n}{m}$D, equal to it, or less; m and n being not particular numbers, but any whatsoever. But if $A = \frac{n}{m}B$, we have $mA = nB$; and thence, according as A is greater than $\frac{n}{m}$B, equal to it, or less, we have mA greater than nB, equal to it, or less; and similarly, mC greater than nD, equal to it, or less. Thus we are brought to Euclid's definition (book v. def. 5), *Εν τῷ αὐτῳ λόγῳ μεγέθη λέγεται εἶναι, πρῶτον πρὸς δεύτερον καὶ τρίτον πρὸς τέταρτον· ὅταν τὰ τοῦ πρώτου καί τριτου ἰσάκις πολλαπλάσια τῶν τοῦ δέυτέρου καὶ τετάρτου ἰσάκις πολλαπλασίων, καθ' ὁποιονοῦν πολλαπλασιασμὸν, ἑκατέρου ἢ ἅμα ἐλλείπη, ἢ ἅμα ἴσα ᾖ, ἢ ἅμα ὑπερεχῃ ληφθέντα κατάλληλα.*

On the foundation of this definition he has constructed, in his sixth book, what appears to us a far more elegant treatise than any by which modern writers of elements have endeavoured to supersede it. That he has been able to accomplish it logically, without even mentioning the existence of incommensurable magnitudes, is the best possible evidence of its perfection.

His tenth book has often been called a treatise of incommensurables, or of surds. Not that Euclid has any mode of expressing abstract surds; but he treats of lines and areas whose relation could not be signified arithmetically without surds. The extent of his doctrines on this subject, in more than a hundred propositions, only embraces relations expressed by square roots, and their union with integral or fractional numbers, including repeated extractions of square roots, so as to produce biquadratic roots, &c. *in infinitum.*

It is manifest that he knew what is expressed in the algebraic formula $\sqrt{A + B} = \sqrt{\{\frac{1}{2}(A + \sqrt{A^2 - B^2})\}} + \sqrt{\{\frac{1}{2}(A - \sqrt{A^2 - B^2})\}}$; or that, as the same may be expressed implicitly, "the square root of A + B is the sum of the square roots of the numbers whose sum is A and product $\frac{1}{4}B^2$;" which gives this geometrical proposition: "The straight line equal in power to the rectangle under a given line, and the sum of two unequal lines, is composed of two straight lines, which are severally equal in power to the rectangles under the given line and those segments of the greater of the unequal lines whose rectangle is a fourth of the square of the less." He discusses with equal fulness the propositions contained in the kindred formula $\sqrt{A - B} = \sqrt{\{\frac{1}{2}(A + \sqrt{A^2 - B^2})\}} - \sqrt{\{\frac{1}{2}(A - \sqrt{A^2 - B^2})\}}$.

This affords a clew to the design of the greater part of the book, and some of the most elegant constructions. In particular, we may discover, in an attentive consideration of these formulæ, the origin of those *hexads* of irrational lines, of which he has been obliged to distinguish some by long and rather uncouth names.

The tenth book of the *Elements* is amongst the very finest performances of antiquity, for subtilty, clearness, and elegance. (O. O. O.)

INCOMMENSURABLE *Numbers* are such as have no common divisor that will divide them both equally.

INCOMPATIBLE, that which cannot subsist with another without destroying it. Thus cold and heat are incompatible in the same subject, the stronger overcoming and expelling the weaker.

INCORPOREAL, spiritual, a thing or substance which has no body. Thus the soul of man is incorporeal, and may subsist independently of the body.

INCORRUPTIBLES, INCORRUPTIBILES, the name of a sect which sprung out of the Eutychians. Their distinguishing tenet was, that the body of Jesus Christ was incorruptible; by which they meant, that after the time in which he was formed in the womb of his mother, he was not susceptible of any change or alteration, not even of any natural and innocent passions or appetites, so that he ate without any occasion, before his death, as well as after his resurrection. And hence it was that they took their name.

INCUBUS, NIGHT-MARE, a disease consisting in an oppression of the chest, so very violent that the patient cannot speak, or even breathe. The word is derived from the Latin, *incubare*, to lie down on any thing and press it. The Greeks call it ἐφιαλτης, *saltator*, leaper, or one that rushes on a person.

In this disease the senses are not quite lost, but drowned and astonished, as are the understanding and imagination; so that the patient seems to think some huge weight thrown on, and ready to strangle him. Children are very liable to this distemper; and so are fat people, and men of much study and application of mind. It is a result of dyspepsia.

INCUMBENT, a clerk or minister who is resident on his benefice, and who is called *incumbent*, because he does, or at least ought to, bend his whole study to discharge the cure of his church.

INCURVATION of the *Rays of Light*, their bending out of a rectilinear course, occasioned by refraction. See OPTICS.

INDEFEASIBLE, a term in law for what cannot be defeated or made void; as an indefeasible estate of inheritance, an indefeasible right, and so on.

INDEMNITY, in *Law*, the saving one harmless; or a writing to secure one from all damage and danger that may ensue from any act.

INDENTURE, in *Law*, a writing which comprehends some contract between two at least, being indented at top, answerable to another part which has the same contents. See DEED.

INDEPENDENTS, a sect of Protestants, so called from their maintaining that each congregation of Christians, with its office-bearers, which meets in one house for public worship, is a complete church; has sufficient power to act and perform every thing relating to religious government within itself; and is in no respect whatever subject or accountable to other churches.

The Independents, like every other Christian sect, derive their origin from the practice of the apostles in planting the first churches; but they were unknown in modern times till they arose in England during the reign of Elizabeth. The hierarchy established by that princess in the churches of her dominions, the vestments worn by the clergy in the celebration of divine worship, the book of common prayer, and, above all, the sign of the cross used in the administration of baptism, were very offensive to many of her subjects, who during the persecution of the former reign had taken refuge amongst the Protestants of Germany and of Geneva. Those men thought that the church of England resembled, in too many particulars, the church of Rome, which they believed to be antichristian; and they called perpetually for a more thorough reformation and a purer worship. From this circumstance they were stigmatised by their adversaries with the general name of *Puritans*, as the followers of Novatian[1] had been in the ancient church. Elizabeth was not disposed to comply with their demands; and it is difficult to say what might have been the issue of the contest had the Puritans been united in sentiments, in views, and in measures. But the case was quite otherwise. That large body, composed of persons of different ranks, characters, opinions, and intentions, and unanimous in nothing but in their antipathy to the forms of doctrine and discipline which were established by law, was all of a sudden divided into a variety of sects. Of these the most famous was that which was formed about the year 1581, by Robert Brown; a man insinuating in his manners, but unsteady and inconsistent in his views and notions of men and things.

This innovator differed not in point of doctrine either from the church of England or from the rest of the Puritans; but he had formed notions, then new and singular, concerning the nature of the church, and the rules of ecclesiastical government. He was for dividing the whole body of the faithful into separate societies or congregations; and maintained, that such a number of persons as could be contained in an ordinary place of worship ought to be considered as a church, and enjoy all the rights and privileges that are competent to an ecclesiastical community. These small societies he pronounced independent *jure divino*, and entirely exempt from the jurisdiction of the bishops, in whose hands the court had placed the reins of spiritual government; and also from that of presbyteries and synods, which the Puritans regarded as the supreme visible sources of ecclesiastical authority. He also maintained that the power of governing each congregation resided in the people, and that each member had an equal share in this government, and an equal right to order matters for the good of the whole society. Hence all points both of doctrine and discipline were submitted to the discussion of the congregation, and whatever was supported by a majority of voices passed into a law. It was the congregation also that elected certain of the brethren to the office of pastors, to perform the duty of public instruction, and the several branches of divine worship; reserving, however, to themselves the power of dismissing these ministers, and reducing them to the condition of private members, whenever they should think such a change conducive to the spiritual advantage of the community. It is likewise to be observed, that the right of the pastors to preach was by no means of an exclusive nature, or peculiar to them alone; since any member who thought proper to exhort or to instruct the brethren was abundantly indulged in the liberty of "prophesying" to the whole assembly. Accordingly, when the ordinary teacher or pastor had finished his discourse, all the other brethren were permitted to communicate in public their sentiments and illustrations upon any useful or edifying subject.

The zeal with which Brown and his associates maintained and propagated these notions was ardent and active. He affirmed that all communion was to be broken off with those religious societies which were founded upon a different plan from his; and treated the church of England more especially as a spurious church, the ministers of which were unlawfully ordained, whilst her discipline was popish and antichristian, and her sacraments and institutions destitute of all efficacy and virtue. The sect of this innovator, not being able to endure the severe treatment which their own zeal had brought upon them from an administration which was not distinguished for its mildness and indulgence, retired into the Netherlands, and founded churches at Middleburg in Zealand, and at Amsterdam and Leyden in the province of Holland. But their establishments were neither solid nor lasting. Their founder returned into England, and having renounced his principles of separation, took orders in the established church, and obtained a benefice. The Puritan exiles, whom he thus abandoned, disagreed amongst themselves, and having split into parties, their affairs gradually declined. This engaged the wiser part of them to mitigate the severity of their founder's plan, and to soften the rigour of his uncharitable decisions.

The person who had the chief merit of bringing about this reformation was one of their pastors, called John Robinson, a man who possessed much of the solemn piety of the times, and no inconsiderable portion of learning. This well-meaning reformer, perceiving the defects which reigned in the discipline of Brown, and in the spirit and temper of his followers, employed the utmost zeal and diligence in correcting them, and in new-modelling the society in such a manner as to render it less odious to its adversaries, and less liable to the censure of those Christians who looked upon charity as the end of the commandments. Hitherto the sect had been called Brownists; but Robinson having, in his Apology, affirmed, "Cœtum quemlibet particularem, esse totam, integram, et perfectam ecclesiam ex suis partibus constantem immediate et *independenter* (quoad alias ecclesias) sub ipso Christo," the sect was henceforth called *Independents*, and the apologist was considered as its founder.

The Independents were much more commendable than the Brownists, whom they surpassed both in the moderation of their sentiments, and in the order of their discipline. They did not, like Brown, pour forth bitter and uncharitable invectives against the churches which were governed by rules entirely different from theirs, nor pronounce them on that account unworthy of the Christian name. On the contrary, though they considered their own form of ecclesiastical government as of divine institution, and as originally introduced by the authority of the apostles, nay, by the apostles themselves, they had yet candour and charity enough to acknowledge that true religion and solid piety might flourish in those communities which were under the jurisdiction of bishops or the government of synods and presbyteries. This is put beyond all doubt by Robinson himself, who expresses his own private sentiments and those of his community in the following clear and precise words: " Profitemur coram Deo et hominibus, adeo nobis convenire cum ecclesiis reformatis Belgicis in re religionis, ut omnibus et singulis earundem ecclesiarum fidei articulis, prout habentur in harmonia confessionum fidei, parati simus subscribere. Ecclesias reformatas pro veris et genuinis habemus, cum iisdem in

[1] The followers of Novatian were called *Puritans*, because they would not communicate with the Catholic church, under pretence that her communion was polluted by admitting those to the sacred mysteries who through infirmity had sacrificed to idols in times of persecution. These unhappy men were not received by the church till after a long course of penance. But the Novatians would not receive them at all, however long their penance, or however sincere their sorrow, for their sin. In other respects, the ancient Puritans were, like the English, orthodox in the faith, and irreproachable in their morals.

sacris Dei communionem profitemur, et, quantum in nobis est, colimus." They were also much more attentive than the Brownists in keeping on foot a regular ministry in their communities; for, whilst the latter allowed promiscuously all ranks and orders of men to teach in public, the Independents had, and still have, a certain number of ministers, chosen respectively by the congregations where they are fixed; nor is any person amongst them permitted to speak in public, before he has submitted to a proper examination of his capacity and talents, and been approved of by the heads of the congregation.

This religious society still subsists, and has produced divines as eminent for learning, piety, and virtue, as any church in Christendom. It is now distinguished from the other Protestant communities chiefly by the two following circumstances: 1. The Independents reject the use of all creeds and confessions drawn up by fallible men, requiring of their teachers no other test of orthodoxy than a declaration of their belief in the gospel of Jesus, and their adherence to the Scriptures as the sole standard of faith and practice. 2. They attribute no virtue whatever to the rite of ordination, upon which some other churches lay so much stress; for the Independents declare, that the qualifications which constitute a regular minister of the New Testament, are a firm belief in the gospel, a principle of sincere and unaffected piety, a competent stock of knowledge, a capacity for leading devotion and communicating instruction, a serious inclination to engage in the important employment of promoting the everlasting salvation of mankind, and ordinarily an invitation to the pastoral office from some particular society of Christians. Where these things concur, they consider a person as fitted and authorized for the discharge of every duty which belongs to the ministerial function; and they believe that the imposition of the hands of bishops or presbyters conveys to him no powers or prerogatives of which he was not before possessed. At the same time it is their custom to impose hands in ordaining pastors, as a token of recognition in a new relation.

When the reformers separated from the church of Rome, they drew up public confessions of faith, or articles of religion, to which they demanded subscription from their respective followers. Their purpose in this was to guard against dangerous heresies, to ascertain the meaning of scriptural language, and, we doubt not, to promote the unity of the spirit in the bond of peace. These were laudable ends; but of the means chosen for attaining them, the late Dr Taylor of Norwich, the glory of the Independent churches, and whose learning would have done honour to any church, expresses his opinion in the following indignant language: "How much soever the Christian world valueth these creeds and confessions, I confess, for my own part, that I have no opinion of them. But we are told that they were generally drawn up by the ablest divines. But what evidence is there of this? are divines in vogue and power commonly the most knowing and upright? But granting that the reformers were in those days the ablest divines; the ablest divines educated in popish schools, notwithstanding any pretended learning, might comparatively be very weak and defective in Scripture knowledge, which was a thing in a manner new to them. In times of great ignorance they might be men of eminence, and yet far short of being qualified to draw up and decide the true and precise rules of faith for all Christians. Yea, their very attempting to draw up, decide, and establish, such rules of faith, is an incontestable evidence of their surprising ignorance and weakness. How could they be able divines, when they imposed upon the consciences of Christians their own decisions concerning gospel-faith and doctrine? Was not this in fact to teach and constrain Christians to depart from the most fundamental principle of their religion, subjection and allegiance to Christ, the only teacher and lawgiver? But if they were able men, were they infallible? No; they publicly affirmed their own fallibility; and yet they acted as if they had been infallible, and could not be mistaken in prescribing faith and doctrine.

"But even if they were infallible, who gave them commission to do what the Spirit of God had done already? Could the first reformers hope to deliver the truths of religion more fully and more clearly than the Spirit of God? Had they found out more apt expressions than had occurred to the Holy Spirit? The Son of God 'spake not of himself; but as the Father said unto him, so he spake' (John, xii. 50). 'The Spirit of truth spake not of himself; but whatsoever he heard, that he spake' (John, xvi. 13). 'The things of God the apostles spake, not in the words which man's wisdom teacheth, but which the Holy Ghost teacheth' (1 Cor. ii. 13). If the Christian revelation was thus handed down to us from the Fountain of Light with so much care and exactness, both as to matter and words, by the Son of God, by the Spirit, and by the apostles, who were the ancient doctors and bishops? or who were the first reformers? or who were any synods or assemblies of divines, that they dared to model Christian faith into their own invented forms, and impose it upon the minds of men in their own devised terms and expressions?

"Has Christ given authority to all his ministers to the end of the world, to new-mould his doctrines by the rules of human learning whenever they think fit? or hath he delegated his power to any particular persons? Neither the one nor the other. His doctrines are not of such a ductile nature; but stand fixed, both as to matter and words, in the Scripture. And it is at any man's peril, who pretends to put them, as they are rules of faith, into any new dress or shape. I conclude, therefore, that the first reformers, and all councils, synods, and assemblies, who have met together to collect, determine, and decide, to prescribe and impose matters pertaining to Christian faith, have acted without any warrant from Christ, and therefore have invaded the prerogative of him who is the sole Prophet and Lawgiver to the church. Peace and unity, I know, is the pretended good design of those creeds and confessions. But as God never sanctified them for these ends, so all the world knows they have produced the contrary effect; discord, division, and the spilling of whole seas of Christian blood, for fourteen hundred years together."

Such sentiments as these are now maintained by Christians of various denominations; but they were first avowed by the Independents, to whom, therefore, the merit or demerit of bringing them to light properly belongs. Our readers will think differently of them according to their preconceived opinions; but it is not our province either to confirm or to refute them. They rise almost necessarily out of the independent scheme of congregational churches; and we could not suppress them without deviating from our fixed resolution of doing justice to all religious parties, as well those from whom we differ as those with whom we agree. It ought not, however, to be rashly concluded that the Independents of the present age, merely because they reject the use of all creeds of human composition, doubt or disbelieve the doctrines deemed orthodox in other churches. Their predecessors in the last century were thought to be more rigid Calvinists than the Presbyterians themselves; as many of those may likewise be who in the present century admit not the confessions and formulas of the Calvinistic churches. They acknowledge as divine truth every doctrine contained in the Scriptures, but they think that scriptural doctrines are most properly expressed in scriptural language; and the same spirit of religious liberty which makes them reject the authority of bishops and synods in matters of discipline, makes them reject the same authority in matters of faith. In either case, to call any man or body of men their masters, would, in their opinion, be a violation of the divine law, since " one is their master, even Christ, and they are all brethren."

In support of their scheme of congregational churches, they observe that the word ἐκκλησια, which we translate *church*, is always used in Scripture to signify either a *single congregation*, or the *place* where a single congregation meets. Thus that unlawful assembly at Ephesus brought together against Paul by the craftsmen is called ἐκκλησια, *a church* (Acts, xix. 32, 39, 41). The word, however, is generally applied to a more sacred use; but still it signifies either the *body* assembling, or the *place* in which it assembles. The whole body of the disciples at Corinth is called *the church*, and spoken of as coming together into *one place* (1 Cor. xiv. 23). The place into which they came together we find likewise called *a church*; " when ye come together in the *church*,—when ye come together into one place" (1 Cor. xi. 18, 20). Wherever there were more congregations than one, there were likewise more *churches* than one. Thus, " Let your women keep silence in the *churches*," ἐν ταις ἐκκλησιαις (1 Cor. xiv. 34). The whole nation of Israel is indeed called a *church*, but it was no more than a single congregation, for it had but one place of public worship, namely, first the tabernacle, and afterwards the temple. The catholic church of Christ, his holy nation and kingdom, is likewise a single congregation, having one place of worship, that is, heaven, where all the members assemble by faith and hold communion; and in which, when they shall all be fully gathered together, they will in fact be one glorious assembly. Accordingly we find it called " the general assembly and church of the first-born, whose names are written in heaven."

Besides these, the Independent can find no other description of a church in the New Testament; not a trace of a diocese or presbytery consisting of several congregations all subject to one jurisdiction. The number of disciples in Jerusalem was certainly great before they were dispersed by the persecution in which Paul bore so active a part. Yet they are never mentioned as forming distinct assemblies, but as one assembly meeting with its elders in one place; sometimes in the temple, sometimes in Solomon's porch, and sometimes in an upper room. After the dispersion, the disciples who fled from Jerusalem, as they could no longer assemble in one place, are never called a church by themselves, or one church, but the *churches* of Judæa, Samaria, and Galilee (Acts, ix. 31; Gal. i. 22). Hence the Independent concludes, that in Jerusalem the words *church* and *congregation* were of the same import; and if such was the case there, where the gospel was first preached, he thinks we may reasonably expect to find it so in other places. Thus, when Paul on his journey calls the elders of the church of Ephesus to Miletus, he speaks to them as the joint overseers of a single congregation: " Take heed to yourselves, and to all the flock over which the Holy Ghost hath made you overseers" (Acts, xx. 28). Had the church at Ephesus consisted of different congregations united under such a jurisdiction as that of a modern presbytery, it would have been natural to say, " Take heed to yourselves, and to the *flocks* over which the Holy Ghost hath made you overseers;" but this is a way of speaking of which the Independent finds no instance in the whole of the New Testament. The sacred writers, when speaking of all the Christians in a nation or province, never call them *the church* of such a nation or province, but *the churches* of Galatia (Gal. i. 2), *the churches* of Macedonia (2 Cor. viii. 1), *the churches* of Asia (1 Cor. xvi. 19). On the other hand, when speaking of the disciples in a city or town, who might ordinarily assemble in one place, they uniformly call them *a church*; as, the church of Antioch, the church at Corinth, the church of Ephesus, and the like.

In each of these churches or congregations there were bishops, sometimes called elders, and deacons; and in every church there seems to have been more than one elder, in some a great many, " who all laboured in word and doctrine." Thus we read (Acts, xiv. 23) of Paul and Barnabas ordaining elders (to be bishops and deacons) in every church; and (Acts, xx. 17) of a company of elders in the church of Ephesus, who were exhorted to " feed the flock, and to take heed to themselves and to all the flock over which the Holy Ghost had made them overseers." But of such elders as are to be found in modern presbyterian churches, who neither teach nor are fit to teach, the Independent finds no vestige in the Scriptures, nor in the earliest uninspired writers of the Christian church. The rule or government of this presbytery or eldership in a church is not their own, but Christ's. They are not lords over God's heritage, nor can they pretend to more power over the disciples than the apostles possessed. But when the administration of the apostles in the church of Jerusalem, and other churches where they acted as elders, is inquired into by an Independent, it does not appear to him that they did any thing of common concern to the church without the consent of the multitude; nay, it seems they thought it necessary to judge and determine in discipline in presence of the whole church (Acts, vi. 1–6, xv. 22; 1 Cor. v. 3, 4, 5). Excommunication and absolution were in the power of the church at Corinth, and not of the elders as distinguished from the congregation (1 Cor. v.; 2 Cor. ii.). The apostle indeed speaks of his delivering some unto Satan (1 Tim. i. 20). But it is by no means clear that he did it by himself, and not after the manner pointed at (1 Cor. v. 4, 5); even as it does not appear, from his saying, in one epistle, that the gift was given unto Timothy by the putting on of *his* hands, that this was not done in the *presbytery* of a church, as in the other epistle we find it actually was. The trying and judging of false apostles was a matter of the first importance; but it was done by the elders with the flock at Ephesus (Rev. ii. 2; Acts, xx. 28); and that whole flock did, in the days of Ignatius, all partake of the Lord's Supper, and pray together in one place.[1] Even the power of binding and loosing, or the power of the keys as it has been called, was by our Saviour conferred, not upon a particular order of disciples, but upon the church. " If thy brother shall trespass against thee, go and tell him his fault between thee and him alone; if he shall hear thee, thou hast gained thy brother. But if he will not hear thee, then take with thee one or two more, that in the mouth of

[1] The evidence upon which this is stated by Mr Glass, for the whole of this reasoning is extracted from his works, is probably the following passage in the epistle of Ignatius to the Ephesians: Ἐι γαρ ἑνος και δευτερου προσευχη, " For if the prayer of one or two be of such force as we are told, how much more prevalent must that be which is made by the bishop and the whole church? He, then, that does not come together into the *same place* with it, is proud, and hath condemned himself; for it is written, God resisteth the proud. Let us not therefore resist the bishop, that we may be the servants of God." The sentence, as it thus stands by itself, certainly countenances Mr Glass's scheme; but the reader who thinks any regard due to the testimony of Ignatius will do well to peruse the whole epistle as published by Vossius.

two or three witnesses every word may be established. And if he shall neglect to hear them, tell it unto the church; but if he neglect to hear the *church*, let him be unto thee as an heathen man and a publican. Verily I say unto you, whatsoever ye shall bind on earth shall be bound in heaven," &c. (St Matth. xviii. 15, 16, 17, 18.) It is not said, if he shall neglect to hear the one or two, tell it to the elders of the church; far less can it be meant that the offended person should tell the cause of his offence to all the disciples in a presbytery or diocese consisting of many congregations. But he is required to tell it to that particular church or congregation to which they both belong; and the sentence of that assembly, pronounced by its elders, is in a very solemn manner declared to be final, from which there lies no appeal to any jurisdiction on earth.

With respect to the constituting of elders in any church or congregation, the Independent reasons in the following manner. The officers of Christ's appointment are either ordinary and permanent in the church, or they were extraordinary and peculiar to the planting of Christianity. The extraordinary were those who were employed in laying the plan of the gospel churches, and in publishing the New Testament revelation. Such were the apostles, the chosen witnesses of our Saviour's resurrection; such were the prophets inspired by the Holy Ghost for explaining infallibly the Old Testament by the things written in the New; and such were the evangelists, the apostles' ministers. These can be succeeded by none in that which was peculiar to them, because their work was completed by themselves. But they are succeeded in all that was not peculiar to them by bishops and deacons, the only two ordinary and permanent orders of ministers in the church. We have already seen that it belongs to the office of the bishop to feed the flock of Christ. The only question to be settled, then, is, How men are ordinarily called to that office? for about the office of the deacon there is little or no dispute. No man now can pretend to be so called of God to the ministry of the word as the apostles and other inspired elders were, whom he chose to be the publishers of his revealed truth, and to whose mission he bore witness in an extraordinary manner. But what the apostles were to those who had the divine oracles from their mouths, that their writings are to us; and therefore as no man can lawfully pretend a call from God to make any addition to those writings, so neither can any man pretend to be lawfully called to the ministry of the word already written, but in the manner which that word directs. Now there is nothing of which the New Testament speaks more clearly than of the characters of those who should exercise the office of bishop in the church, and of the actual exercise of that office. The former are graphically drawn in the epistles to Timothy and Titus; and the latter is minutely described in St Paul's discourse to the Ephesian elders, in St Peter's exhortation to elders, and our Lord's commission to those ministers with whom he promised to be always present even unto the end of the world. It is not competent for any man or body of men to add to or take from the description of a gospel minister given in these places, so as to insist upon the necessity of any qualification which is not there mentioned, or to dispense with any qualification as needless which is there required. Neither has Jesus Christ, the only legislator to the church, given to any ministers or people any power or right whatsoever to call, send, elect, or ordain, to that office, any person who is not qualified according to the description given in his law; nor has he given any power or right to reject the least of them who are so qualified, and who desire the office of a bishop or elder. Let a man have hands laid upon him by such as could prove an uninterrupted descent by imposition of hands from the apostles; let him be set apart to that office by a company of ministers themselves, the most conformable to the Scripture character; and let him be chosen by the most holy people on earth; yet if he answer not the New Testament description of a minister, he is not called of God to that office, and is no minister of Christ, but is indeed running unsent. No form of ordination can pretend to such a clear foundation in the New Testament as the description of the persons who should be elders of the church; and the laying on of hands is of small importance in the mission of a minister of Christ; for now, when the power of miracles has ceased, it is obvious that such a rite, by whomsoever performed, can convey no powers, whether ordinary or extraordinary. Indeed it appears to have been sometimes used, even in the apostolic age, without any such intention. When St Paul and St Barnabas were separated to the particular employment of going out to the Gentiles, the prophets and teachers at Antioch "prayed and laid their hands on them." But did this ceremony confer upon the two apostles any new power or authority to act as ministers of Christ? Did the imposition of hands make those shining lights of the gospel one whit better qualified than they were before to convert and baptize the nations, to feed the flock of God, to teach, rebuke, or exhort, with all long-suffering and patience? It cannot be pretended that there was any special virtue in this ceremony. St Paul and St Barnabas had undoubtedly received the Holy Ghost before they came to Antioch; and as they were apostles, they were of course authorized to discharge all the functions of the inferior and ordinary ministers of the gospel. As in this instance, however, the imposition of hands appears to have been a mark of recognition of the parties as qualified for the work to which they were appointed, so Independents usually lay on the hands of the bishops with the same intent. In a word, whoever in his life and conversation is conformable to the character which the inspired writers give of a bishop, and is likewise qualified by his "mightiness in the Scripture" to discharge the duties of that office, is fully authorized to administer the sacraments of baptism and the Lord's Supper, to teach, exhort, and rebuke, with all long-suffering and doctrine, and has all the call and mission which the Lord now gives to any man; whilst he who wants the qualifications mentioned has not God's call, whatever he may have, nor any authority to preach the gospel of Christ, or to dispense the ordinances of his religion.

From this view of the Independent principles, which is faithfully taken from their own writers, it appears that, according to them, even the election of a congregation confers upon the man whom they may choose for their pastor no new powers, but only creates a new relation between him and a particular flock, giving him an exclusive right, either by himself or in conjunction with other pastors constituted in the same manner, to exercise among them that authority which he derives immediately from Christ, and which, in a greater or less degree, is possessed by every sincere Christian according to his gifts and abilities. Were the ministers of the gospel constituted in any other way than this; by imposition of hands, for instance, in succession from the apostles; the case of Christians would, in the opinion of the Independents, be extremely hard, and the ways of God scarcely equal. We are strictly commanded not to forsake the assembling of ourselves together, but to continue stedfast in the apostles' doctrine and fellowship, and in the breaking of bread, and in prayer. "But can any man," asks one of their advocates, "bring himself to believe, that what he is commanded to do in point of gratitude, what is made his own personal act, an act expressive of certain dutiful and pious affections, can possibly be restricted to the intermediate offices or instrumentality of others, who act by powers which he can neither give nor take away? To suppose a thing necessary to my happiness, which is not in my own power, or wholly depends upon the good pleasure of another, over whom I have no authority, and concerning whose intentions and dispositions I can have no security, is to suppose a constitution the most foolish and ill natured, utterly inconsistent with our ideas of a wise and good agent." Such are some of the principal arguments by which the Independents maintain the divine right of congregational churches. For many years the numbers of this denomination of Christians have been increasing, especially in England; and it is calculated that they have now nearly 1600 congregations in England and Wales. They have only about eighty in Scotland, and thirty in Ireland; but it is reckoned that they have nearly a thousand congregations in America.

Sir James Mackintosh, in his *Historical Fragment*, gives a short notice of this body. "They disclaimed the qualifications of 'national,' as repugnant to the nature of 'a church.' The religion of the Independents could not, without destroying its nature, be established by law. They never could aspire to more than religious liberty, and they accordingly have the honour to be the first, and long the only, Christian community who collectively adopted that sacred principle. It is true, that in the beginning they adopted the pernicious and inconsistent doctrine of limited toleration, excluding Catholics as idolators, and, in New England, where the great majority were of their persuasion, punishing even capitally dissenters from opinions which they accounted fundamental. But as intolerance could promote no interest of theirs, real or imaginary, their true principles finally worked out the stain of these dishonourable exceptions. The government of Cromwell, more influenced by them than by any other persuasion, made as near approaches to general toleration as public prejudice would endure; and Sir Harry Vane, an Independent, was probably the first who laid down, with perfect precision, the inviolable rights of conscience, and the exemption of religion from all civil authority."[1]

INDERABIA, or ANDERABIA, a small island near the mouth of the Persian Gulf. It is separated from the mainland by a strait about three miles in length, three in breadth, and free from danger. It is a low, level, and narrow island, about three miles in length. Ships running for shelter under this island must not come within a mile of its south end, until a remarkable tree, which will be distinguished by itself, bears west-north-west. Lat. 26. 40. N.

INDETERMINATE, in general, an appellation given to whatever is not certain, fixed, and limited; in which sense it is the same with *indefinite*.

INDEX, in *Anatomy*, denotes the fore finger. It is so called from *indico*, I point or direct, because that finger is generally so used; and hence also the extensor indicis is called *indicator*.

INDEX, in *Arithmetic* and *Algebra*, shows to what power any quantity is involved, and is otherwise called its *exponent*. See ALGEBRA.

INDEX of a Book, is that part annexed to a book, referring to the particular matter or passages therein contained.

INDEX of a Globe, is a little style fitted on to the north pole, and turning round with it, pointing to certain divisions in the hour-circle. It is sometimes also called *gnomon*. See GLOBE.

INDEX EXPURGATORIUS, a catalogue of prohibited books at Rome.

INDIA. The general name of India has always had a very wide and rather indefinite application, both in ancient and modern times. It has been generally used to designate all those vast regions of the Asiatic continent which lie to the eastward of the Indus, which were accordingly distinguished by the ancients into two great divisions, namely, *India intra Gangem*, and *India extra Gangem*. The meaning of the name, which has long been a source of perplexity to the learned, has never been clearly ascertained. It is supposed to be of Persian origin, from the word Hind, or Heando, the term in the more ancient languages of Persia, which has been employed by the Greeks and Romans, and from them made its way into the modern languages of Europe. The progress of ancient discovery in India has been already narrated in our account both of Asia and Hindustan. Prior to the expedition of Alexander, all the knowledge which the Greeks possessed of India was derived from the report of the Persians. The geographical writers of ancient times, Eratosthenes, Strabo, and Pliny, procured more correct information from Alexander's officers; and in later times the ancients extended their knowledge of India by means of commerce. The general notion of the boundaries of India within the Ganges appears to have been correct. On the north they stated the boundary to be a range of mountains, the modern Himalaya, which they considered to be the extremity of the range of Mount Taurus, and which were named Paropamesus by the natives, or the mountains of Emodus and Imaus. The Indus was pointed out as the western boundary; and in later times, when the knowledge of Indian geography was extended, the Ganges was considered the boundary on the east, and the ocean on the south. Of the form and limits of this extensive region, known under the general appellation of India, the ancients entertained very erroneous notions. Of the country that lay between the Indus and the Ganges they had begun to acquire from travellers more accurate information; but their accounts respecting Southern India was still imperfect. The different geographical writers enumerate many distinct tribes who were scattered over the country between the Indus and the Ganges; but they seem not to have had sufficient information for such a classification of the inhabitants; and little instruction is conveyed concerning India in such a list of uncouth names. Of India beyond the Ganges the ancients are still more imperfectly informed, nor do they seem to have affixed any limits to its extension eastward.

This term of India has been applied with great latitude by modern geographers, not only to Hindustan, but to the countries eastward as far as China, including Arracan, Ava, Cassay, Cachar, Pegu, Tongho, Martaban, Junkseylon, Tavay, Tenassarim, Lowashan, Yemshar, and all the other districts really or nominally subordinate to the Burman empire; also Siam, Malacca, Cambodia, Siampa, Laon, Cochin China, and Tunquin. It includes, in short, all those extensive countries that lie between the Indus on the west and China on the east, and that are bounded on the north by Bukharia and Thibet, on the south by the Indian Ocean and the Bay of Bengal, and on the north-east by the Chinese Sea. A particular description of Hindustan, and of all these other countries, will be found under their respective titles, to which therefore the reader is referred.

INDIA Company. See COMPANY.

INDIA Rubber. See CAOUTCHOUC.

INDIAN, in a general sense, denotes any thing belonging to the Indies, East or West.

INDIAN ISLAND lies on the coast of New Zealand, on the south point of Dusky Bay, and is about four miles in circumference.

---

[1] *View of the Reign of James II.* p. 166.

INDIANA, one of the United States of North America, is bounded on the north by Lake Michigan, and the territory of the same name; on the south by Kentucky; on the east by Ohio; and on the west by Illinois. It extends from Lat. 37° 50′ to Lat. 41° 45′ north; and from Long. 84° 45′ to Long. 88° west; being 270 miles in length, 220 in breadth, and containing a superficies of 36,000 square miles. Although this state is more hilly than Illinois, it contains no mountains of any great height. The southern front has the usual belt of river hills, bluffs, and knobs, known by the name of Ohio Hills, which often rise immediately from the waters of the Ohio, in forms of picturesque grandeur and beauty, and sometimes retreat from it to a considerable distance, leaving between the river and their base, a bottom of two or three miles in extent. A range of hills, called the Knobs, stretching from the Ohio to White River of the Wabash, forms the limits of the table lands which separate the waters of the Ohio from those of White River. North of the Wabash, the hills which bear the same name, are precipitous, and the country is to a considerable extent broken and rugged. Large portions of the state may be pronounced hilly, but three-fifths of it at least consist of vast tracts of level country. The wide extent of land watered by the White River is for the most part level. The prairies, so characteristic of the New World, have the usual distinction of high and low, swampy and alluvial. They differ in no respect from those of Illinois, being alike rich, level, and prolific of grass and flowering plants. Those which are situated along the course of the Wabash have been particularly admired for their beauty and fertility. Many of the prairies are long and narrow, some of them, like those of Illinois, are larger than can be taken in at once by the eye, and others are only large enough for a few farms. They are usually bounded by dense forests, and are not unfrequently adorned with copses of small trees. In spring and summer, the luxuriant growth of grass and fragrant flowers, with which they are covered, rises to from six to eight feet in height. For a considerable extent on the northern frontier of the state, between the Wabash and Lake Michigan, the country is for the most part an extended plain, alternately prairie and woodland, diversified by swamps, and by small lakes and ponds. No part of the western world presents larger tracts of rich land, than that portion of White River country, of which Indianopolis, the capital of the state, is the centre. The river or low prairies are levels destitute of timber, and are said to exhibit vestiges of former cultivation. The high or upland prairies are elevated from thirty to one hundred feet above the others, and are far more numerous and extensive. The ordinary depth of the vegetable soil is from two to five feet, but in some places it has been found to extend twenty-two feet downwards. The forest trees, shrubs, plants, and grasses, do not materially differ from those of Illinois, but there is a much greater proportion of beech timber. The principal productions of the state are wheat, Indian corn, rye, oats, barley, buckwheat, and potatoes. There are some prairies and "bottoms" too rich for growing wheat, until the natural wild luxuriance of the soil has been somewhat reduced by cropping. Upland rice has been cultivated with success, and some of the more sheltered and warm valleys have, in favourable years, yielded considerable crops of cotton. This state is exceedingly well adapted for rearing the finest fruits, and fruit-bearing shrubs. There are in many places abundance of wild berries; and on some of the prairies the strawberries are large and fine. It is stated that in the low prairies in the northern parts, whole tracts are covered with the beautiful fowl meadow-grass, the *Poa pratensis* of the north. But wherever the natural prairie grass has been destroyed by being pastured by domestic animals, it is succeeded by the blue grass of the western country, which furnishes not only a beautiful sward, but covers the ground with a carpeting of rich fodder, not unlike the second crop, which is cut in the northern states as the most valuable kind of hay. For all the objects of farming, and raising of grain, hemp, tobacco, and other necessaries, and the rearing of cattle, sheep, swine, horses, as well as other animals, the emigrant could not find a more advantageous country than Indiana. In the rich "bottoms" of the southern parts, the reed cane, and uncommonly large ginseng, are abundant.

This state possesses a great number of rivers and springs, very happily distributed over the country. Their origin is generally to be traced to swamps or lakes, and the surrounding districts are too low and wet for cultivation. The southern extremity is well watered throughout its whole length by the Ohio; and into this noble stream a considerable number of tributaries flow. But the chief river of Indiana is the Wabash, which, after Tennessee, is one of the most considerable tributaries of the Ohio. It traverses the central parts of the state, and, by its extensive branches, irrigates a great portion thereof. White River enters the Wabash from the eastern side, sixteen miles below Vincennes. It is the most considerable tributary of the Wabash, and one of the most important rivers of the state. It waters a vast tract of very fertile country, in a lateral direction to the main stream. It receives a great number of considerable tributaries from the west, and several smaller ones enter it from the eastern side. White Water, which rises in Ohio, waters a large portion of fertile country. The northern frontier of the state, bordering on the territory of Michigan, and the lake of the same name, is watered copiously by rivers which discharge their waters into that lake and Lake Erie. The courses of these streams are generally short, but they carry along large volumes of water. Most of them have their origin in lakes and ponds, of which above one hundred exist along the northern frontier. Many of them have the peculiar character of the waters in this region; that is, they are situated on an elevated plateau, from one extremity of which the waters are discharged into the lakes, and from the other into the waters of the Mississippi. The amount of inland navigation of Indiana is great, although it is not equal to that of Illinois. It possesses the whole extent of the Wabash and White River, with its numerous branches navigable by fly-boats. A navigable canal now connects the White Water with the Ohio, at Cincinnati; others are either completed, in progress, or in contemplation; and, as the wealth and commerce of the state increase, it will emulate the enterprise, the canals, and the great public works of the sister state of Ohio. The whole recent extent of inland navigation which it enjoys may be fairly computed at 5000 miles. A great national road, passing from east to west through the state, is in progress, and a rail-road, from Ohio to Lake Michigan, has been projected.

The climate of Indiana resembles that of Illinois, and the other neighbouring states. That part of it which is contiguous to Lake Michigan is subject to copious rains, and, being otherwise low and marshy, much of the land is unfit for cultivation. For a considerable distance from the lake, sand heaps covered with a few stunted junipers, and swept by the gales of the lake, give little promise of a fine country or propitious climate. But beyond the point to which the breezes of the lake extend, the climate is mild and temperate. The state in general is rather less exposed than Illinois to the extremes of heat and cold. The climate is in general healthy; indeed, the astonishing increase of the population within a few years, affords a proof of this. The higher regions are, of course, more so than those which are low and are swampy. The winters are mild, compared with those of New England or Pennsylvania. Winter commences in its severity about Christmas, but seldom lasts longer than six weeks. During this period, the rivers which have not very rapid currents are frozen; although

Indiana.

winters occur in which the Wabash cannot be crossed upon the ice. Snow does not fall to any great depth; in the middle and southern parts rarely more than six inches. Peach trees are generally in blossom early in March, and the foliage of the forest assumes its green tint in the middle of April.

The interior and northern parts of this state are abundantly stocked with game. Bears, and especially deer, are common. Wild turkeys abound, and prairie hens, partridges, and grouse are seen in countless numbers. The streams, especially those which communicate with Lake Michigan, are stocked with fish of various kinds and the best qualities. Venomous reptiles are sometimes met with, most commonly in the vicinity of ledges of rocks. The rattlesnake and the copper-head are the most numerous and dangerous.

There are salt springs in different parts of the state, but they do not appear to be wrought to any extent. Stone-coal of the best quality is found in various places. Native copper has been discovered in small masses, in the northern parts of the state. Iron-ore is also found in some places. But in general it is too level a country to afford many minerals.

Like Alabama and Tennessee, this state abounds with subterranean wonders, such as caves. Many of these have been explored, and some of them have been described. One of them is generally known in the western country by the name of the *Epsom Salts Cave*. It is situated at a short distance from Jeffersonville. When first discovered, the salts were represented as being some inches deep on the floor. The interior of this cave possesses the usual domes and chambers of extensive caverns, through which the visitant gropes his way inwards for a mile and a quarter, till he reaches the Pillar, which is a splendid column, 15 feet in diameter, and 25 feet in height, regularly reeded from top to bottom. Near it are smaller pillars having the same appearance. The salt in question is sometimes found in lumps, varying from one to ten pounds. The floor and walls are covered with it in the form of frost-work, which, when removed, is speedily reproduced. The earth yields from four to twenty pounds to the bushel, and the product is said to be of the best quality. Nitre is also found in the cave in great abundance; and likewise sulphate of lime, or plaster of Paris.

With regard to the towns of this state, to enumerate all that have attained some degree of importance, would only be to present a barren catalogue of names. We shall shortly describe the principal of these, beginning with Lawrenceburgh, on the south-eastern angle of the state. This town, the seat of justice for the county of Dearborn, stands on the northern bank of the Ohio, twenty-three miles below Cincinnati, and two miles below the Big Miami, the eastern limit of the state. It is situated in the centre of a rich "bottom," and since its commencement has made very rapid progress. Its position in relation to the river, the rich adjacent country, and the Big Miami, is highly eligible. Many of the houses are handsome, and have a fine appearance from the river. There are a number of respectable manufactories, and every thing promises a large and populous town at no distant date. At present the inhabitants are above 1000 in number. Vevay, the seat of justice for Switzerland county, is situated forty-five miles below Cincinnati. It contains between two and three hundred dwelling-houses, a court-house, jail, academy, a printing-office, from which issues a weekly journal, and a branch of the bank of Indiana, besides other public buildings. In the neighbourhood of this town there is the largest vineyard in the United States. Vines have been cultivated to a great extent, and with a success unrivalled in the western world. The inhabitants are chiefly emigrants from Switzerland, who brought with them, from the vine-clad mountains of their native country, those simple manners, and those habits of industry and perseverance, for which that people are distinguished. They are constantly making improvements in the cultivation of the grape, and the wine made from it is of a very superior quality. The Swiss have created some manufactures peculiar to themselves, particularly that of straw-hats. Madison, a populous and thriving town, situated on the Ohio, and nearly equidistant from Louisville and Cincinnati, was commenced in the year 1811. Its position on the Ohio is peculiarly favourable, as it is the point of the river nearest to Indianapolis, and the landing-place for the imports from the Ohio to a number of the newly-settled and thriving counties. Besides churches and public buildings, it has nearly thirty stores of dry-goods, many of which transact extensive business. Large exports of the produce of the country are made here, and the town is particularly noted for the quantity of pork which is barrelled in it. It contains above 2000 inhabitants. Jeffersonville, which is situated just above the Falls of Ohio, is a considerable and handsome village. Four miles and a half below it stands New Albany, the seat of justice for Floyd county. It has a convenient yard for building steam-boats, and is a thriving and busy village, containing about 2000 inhabitants. Passing over some places of minor note, we come to Corydon, the seat of justice for the county of Harrison, and once the political metropolis of the state. It is situated in the forks of Indian Creek, about twenty-three miles from Jeffersonville, and thirteen miles from Ohio. Salem, which is situated on a small branch of Blue River, thirty-four miles north of Corydon, is a flourishing country town, containing above one hundred houses. Vincennes, one of the oldest places in the western world, was settled by French emigrants in the beginning of the last century. It is situated 150 miles above the mouth of the Wabash, and fifty-four from the nearest point of the Ohio. It contains above 300 dwelling-houses, a number of public buildings, and about 1500 inhabitants. Harmony lies fifty-four miles below Vincennes, and sixteen miles from the nearest point of the Ohio, on a rich and heavily-wooded plateau, or second "bottom." It is situated on high ground, is healthy, has a fertile soil, and is in the vicinity of small and rich prairies. It was first settled in 1814 by a religious sect of Germans, denominated Harmonites. They settled first in Pennsylvania, whence they moved in a body, amounting to 800 persons, to this place. Like the primitive Christians, they held their property in common, and their lands were laid off with all the regularity which the compass and square could give to them. For some time they laboured industriously and in perfect peace, but their eyes ultimately began to revert to the temperate climate and the rich savannahs where they had first settled. Whilst under the influence of these yearnings, the leader of a new sect appeared amongst them. This was Robert Owen of New Lanark, in Scotland, the expounder of a new social system. He purchased a large portion of territory, together with a village, and in a short period from seven to eight hundred persons were admitted members of the new establishment. For some time matters seemed to promise fair for the success of the experiment, but it finally shared the fate of the former settlement, as well as that of every other by which theorists would attempt to divert the stream of things from its natural course. The social system is now abandoned. Brookville, which is situated in the Forks of the White River, contains about 100 houses. The surrounding country is well timbered and watered. The soil is rich and productive, and has acquired celebrity on account of the excellence of the tobacco which it produces. Harrison is situated on the north bank of White River, eight miles from its mouth, and eighteen north-east of Brookville, in the centre of an excellent tract of land. The village is divided between the jurisdiction of Indiana and Ohio. In the rich and extensive "bottoms" which surround this place are found great numbers of Indian mounds, containing human bones, axes, vases, and various other implements of war and domestic utensils. Indianapolis, the seat of the government of the state, is situated on the western bank of White River, nearly in the centre of the state, and at a point accessible by steam-boats, in the ordinary state of the Wabash. It is surrounded by one of the most extensive and fertile tracts in North America, and it is being settled with unexampled rapidity. A few years have been sufficient to convert it from a deep and almost impenetrable forest into a populous town and a cultivated country. There are several excellent public buildings, and many comfortable dwelling-houses. In course of time Indianapolis will no doubt become one of the largest towns between Cincinnati and the Mississippi.

This state was admitted into the Union in 1816, when its present constitution was formed. It does not essentially differ from those of the other western states. A governor and lieutenant-governor are chosen by the people triennially. There is a general assembly, consisting of a senate, the members of which are chosen for periods of three years, a third part being elected annually; and of a house of representatives, the members of which are elected annually. The number of representatives may be increased to onc hundred, and of senators to fifty; but at present they do not amount to much more than the half of these numbers. The judges of the supreme court are appointed by the governor, with the consent of the senate; the presidents of the circuit courts by the legislature; and the associate judges are elected by the people. A thirty-sixth part of the land in each township is reserved, by a compact between the state and the rest of the Union, for the support of education; and reservations of land have been made for the support of a college, which is established at Bloomington. Very considerable interest is taken in the cause of education throughout this state. Schools arc established in all the considerable towns and villages, and many of them have a reading-room and library. An historical society has been formed, the object of which is to collect and preserve the antiquities of the state.

This part of the country was first colonized by some French soldiers of Louis XIV., who settled at Vincennes as early as 1702. For nearly a century this solitary colony remained isolated from the rest of mankind, and even retrograded towards the state of the savages who surrounded it, and with whom the colonists intermarried. During the revolution, they manifested a disposition so favourable to the republic, that the general government ceded a tract of land to them at the termination of the war. The savages, however, continued to harass them until the peace, which was restored by the treaty of Greenville. The greater part of the territory was still claimed by the natural heirs of the soil; but in 1811, in consequence of their depredations and murders, a military force was sent against them, and they were defeated in the bloody battle of Tippecause. Since the peace they have been quiet, and have ceded the greater part of their lands to the United States. The remnants of several tribes still remain, and possess either lands or annuities from government. Their numbers may amount to about 5000.

The increase of population in this state has been unusually rapid. In 1820, the inhabitants amounted to 147,000, and the census of 1830 states them to be 344,000, but this number include only persons resident in the state. The revenue for 1831 was 103,000 dollars, and the expenditure 37,765 dollars. (R. R. R.)

INDICATION, in *Physic*, whatever serves to direct the physician how to act.

INDICATIVE, in *Grammar*, the first mood or mode of the verb, by which we simply affirm, deny, or ask something, as, *amant*, they love; *non amant*, they do not love; *amant ne?* do they love? See GRAMMAR.

INDICTION, in *Chronology*, a cycle of fifteen years.

INDICTMENT, in *Law*, one of the modes of prosecuting an offender. In English law, it is a written accusation of one or more persons of a crime or misdemeanor, preferred to, and presented upon oath by, a grand jury. In Scotch Law, it is the name of the summons, or libel, upon which criminals are cited to take their trial before the High Court of Justiciary, and is drawn in the form of a syllogism.

INDIGENOUS, from *indigena*, denotes a native of a country, or that which was originally born or produced in the country where it is found. In this sense, particular species of animals and plants are said to be *indigenous* to the country where they are native; in opposition to EXOTIC.

INDIGESTION, a crudity or want of due coction of the food in thc stomach.

INDIGETES, a name which the ancients applied to some of their gods.

There are various opinions concerning the origin and signification of this word. Some pretend that it was given to the gods in general; others, that it was only applied to the demigods, or great men deified. Some say that it was given to such gods as were originally of the country, or rather such as were the gods of the country which bore this name; whilst others hold that it was ascribed to such gods as were patrons and protectors of particular cities; and others again contend that *indigetes* was derived from *inde genitus* or *in loco degens*, or from *inde* and *ago*, for *dego*, I live, I inhabit; an opinion which seems to be the most probable of all.

In effect it appears, that these *indigetes* were also called *local gods* (*dii locales*), or *topical gods*, which is the same thing; that the *indigetes* were ordinarily men deified, who indeed were in effect local gods, being esteemed the protectors of those places where they were deified; that Virgil joins *patrii* with *indigetes*, as being the same thing (*Georg.* i. ver. 498.), thus *dii patrii, indigetes*; and that the gods to whom the Romans gave the name of *indigetes* were, Faunus, Vesta, Æneas, Romulus, all the gods of Italy, Minerva at Athens, and Dido at Carthage. It is truc, we meet with Jupiter *indiges*; but that Jupiter *indiges* is Æneas, not the great Jupiter, we may see in Livy (lib. i. cap. 3.); and in this last sense Servius assures us that *indiges* comes from the Latin *in diis ago*, I am amongst the gods.

Amongst these *indigetes* gods, there was none more celebrated, or more extensively worshipped, than Hercules.

INDIGO, a dye prepared from the leaves and small branches of the *Indigofera tinctoria*.

This plant requires a smooth rich soil, well tilled, and not too dry. The seed of it, which, in figure and colour, resembles gunpowder, is sown in little furrows that are about the breadth of thc hoe, two or three inches deep, at the distance of a foot from each other, and in as straight a line as possible. Continual attention is required to pluck up the weeds, which would soon choke the plant. Though it may be sown in all seasons, the spring is commonly preferred. Moisture causes this plant to shoot above the surface in three or four days. It is ripe at the end of two months. When it begins to flower, it is cut with pruning-knives; and cut again at the end of every six weeks, if the weather happen to be a little rainy. It lasts about two years, after which term it degenerates, and is then plucked up, and planted afresh. As this plant soon exhausts the soil, because it does not absorb a sufficient quantity of air and dew to moisten the earth, it is of advantage to the planter to have a vast space which may remain covered with trees, till it become necessary to fell them in order to make room for the indigo.

Indigo is distinguished into two kinds; the *true* and the *bastard*. Though the first is sold at a higher price on account of its superiority, it is usually advantageous to cultivate the other, because it is heavier. The first will grow in many different soils; the second succeeds best in those which are most exposed to the rain. Both are liable to great accidents. Sometimes the plant becomes dry, and is destroyed by an insect frequently found on it; at other times, the leaves, which are the valuable part of the plant, are devoured in the space of twenty-four hours by caterpillars. This last misfortune, which is but too common, has given occasion to the saying, that the planters of indigo go to bed rich, and rise in the morning totally ruined.

This production ought to be gathered in with great precaution, for fear of making the farina that lies on the leaves, and is very valuable, fall off by shaking it. When gathered, it is thrown into the steeping-vat, which is a large tub filled with water. Here it undergoes a fermentation, which in twenty-four hours at furthest is completed. A cock is then turned to let the water run into the second tub, called the *mortar* or *pounding-tub*. The steeping-vat is then cleaned out, that fresh plants may be thrown in; and thus the work is continued without interruption.

The water which has run into the pounding-tub is found impregnated with a very subtile earth, which alone constitutes the dregs or blue substance that is the object of this process, and which must be separated from the useless salt of the plant, because this makes the dregs swim on the surface. To effect this, the water is forcibly agitated with wooden buckets, which are full of holes and fixed to a long handle. This part of the process requires the greatest precautions. If the agitation be discontinued too soon, the part that is used in dyeing, not being sufficiently separated from the salt, would be lost. If, on the other hand, the dye were to be agitated too long after the complete separation, the parts would be brought together again, and form a new combination; and the salt reacting on the dregs would excite a second fermentation, that would alter the dye, spoil its colour, and make what is called *burnt indigo*. These accidents are prevented by a close attention to the least alterations which the dye undergoes, and by the precaution which the workmen take to draw out a little of it from time to time in a clean vessel. When they perceive that the coloured particles collect by separating from the rest of the liquor, they leave off shaking the buckets, in order to allow time to the blue dregs to precipitate to the bottom of the tub, where they are left to settle till the water is quite clear. Holes made in the tub, at different heights, are then opened one after another, and the useless water is let out.

The blue dregs remaining at the bottom having acquired the consistence of a thick muddy liquid, cocks are then opened, which draw it off into the settler. After it is still more cleared of much superfluous water in this third and last tub, it is drained into sacks, from which, when water no longer filters through the cloth, this matter, now become of a thicker consistence, is put into chests, where it entirely loses its moisture. At the end of three months the indigo is fit for sale.

It is used, in washing, to give a bluish colour to linen; painters also employ it in their water colours; and dyers cannot make fine blue without indigo. The ancients procured it from the East Indies; in modern times, it has been transplanted into America.

INDIVIDUAL, a particular being of any species, or that which cannot be divided into two or more beings equal or alike.

The usual division in logic is made into *genera;* those *genera* into *species;* and those *species* into *individuals.*

INDIVISIBLE, amongst metaphysicians. A thing is said to be absolutely *indivisible,* that is, a simple being, when it consists of no parts into which it can be divided. Thus, God is *indivisible* in all respects; as is also the human mind, not having extension, nor other properties of body.

INDIVISIBLES, in *Geometry*, the elements or principles into which any body or figure may be ultimately resolved, which elements are supposed to be infinitely small. Thus, a line may be said to consist of points, a surface of parallel lines, and a solid of parallel and similar surfaces.

INDORSEMENT, in *Law*, any thing written on the back of a deed; as a receipt for money received.

There is likewise an *indorsement*, by way of assignment, on bills of exchange and notes of hand; which may be done by merely writing a person's name on the back of the instrument.

INDRE, a department of France, formed out of a part of the ancient Touraine, and a portion of the province of La Marche. It is an inland division, surrounded on every side by other departments of the kingdom. The extent is 2925 square miles, or, according to the *Royal Almanac*, 702,240 hectares, of which 441,383 are under the plough, 14,025 are vineyards, 36,696 pastures, 10,409 commons, 104,568 waste heaths, 57,343 woods and forests, 5059 gardens, and the remainder consists of the sites of cities, towns, and villages, and of roads, rivers, and canals. It is divided into 4 arrondissements, and these are subdivided into 23 cantons, and 275 communes, with a population of 207,721 individuals, all professing the Catholic religion, and having 166 churches. It is a level district, with but few hills, and only such valleys as receive the several streams which run through them. On the southern boundary there is a range of hills, not lofty, composed of granite and slate, but they rather belong to the department of the Cher. The department is watered by no less than 15 rivers, and 100 subsidiary brooks. The principal streams are the Creuse, the Indre, the Fouson, and the Arnon. The climate is temperate, neither the heat nor the cold being excessive, but in the vicinity of the more sluggish streams there is a moisture in the air, deemed unfavourable to health. The department is very backward in its agriculture, and the farms are mostly small, being let on the Metayer system, and the rent being paid by a stipulated portion of the crops. The common rotation is a fallow and two crops of corn. The yearly produce, wheat and rye, is about equal, and of both, as well of barley and oats, there is a surplus. The vineyards, though extensive, are neglected, and the wine is badly managed, and of little repute. The manufactures are chiefly of the domestic kind, and supply the inhabitants with clothing and household and rural implements. The capital is Chateauroux, with 8500 inhabitants.

INDRE and LOIRE, a department of the north-west of France, formed out of the ancient district of Touraine. It extends over 2953 square miles, or, according to the *Royal Almanac*, 612,679 hectares. It is divided into three arrondissements, whose subdivisions are 24 cantons, and 311 communes, with 274,970 inhabitants. It is generally a level country, consisting of valleys, in which the rivers run, and of plains between, of moderate elevation, which, from their good cultivation and fertility, have been denominated the garden of France. There are, however, some parts of the department which are sandy heaths, and others where the chalk is so slightly covered with soil, as to render it unfit for profitable cultivation. It is well watered by the rivers Loire, Cher, Indre, Vienne, and the Creuse, and their respective tributary brooks, too numerous to be recounted. The climate is temperate like all the middle of France, with a pleasant spring and autumn, hot summer, and short but not severe winter. The forests cover one-ninth of the department, producing fuel and timber. The corn of this division is unequal to the consumption, one-fourth of which must be supplied from the neighbouring provinces. It yields, however, a surplus of each kind of domestic animals, and of their produce, and a most copious store of fruits of all kinds, some of which dried, as plums and apples, and others as almonds, filberts, walnuts, and chestnuts, with no preparation, form a considerable branch of commerce. It yields also good flax and hemp, and much honey and wax. The wine is chiefly white, and some of it, as well as of the red, is highly valued, but the greater part is made into brandy for distant markets. The rearing silk worms, which was once a considerable occupation, has been nearly abandoned. There are some mines of iron, whose ores are cleared and worked into the appropriate articles. The manufactures are inconsiderable, consisting of linen and woollen cloth, of some silk goods, paper, liquorice, and liqueurs. The capital of the department is the city of Tours.

INDUCTION, in *Logic* and *Rhetoric*, a consequence drawn from several propositions or principles first laid down; or a general inference deduced from a number of facts so arranged in the statement of them as to lead necessarily to the conclusion.

Induction, in *Law*, is putting a clerk or clergyman in possession of a benefice or living to which he is collated or presented.

Induction, in *Philosophy*. See Physics.

INDULGENCES, in the Roman Catholic church, are a remission of the punishment due to sins, granted by the church, and supposed to save the sinner from purgatory.

According to the doctrine which was once maintained by this church, all the good works of the saints, over and above those which were necessary towards their own justification, are deposited, together with the infinite merits of Jesus Christ, in one inexhaustible treasury, the keys of which were committed to St Peter, and to his successors the popes, who might open it at pleasure, and by transferring a portion of this superabundant merit to any particular person, for a sum of money, convey to him either the pardon of his own sins, or a release for any one in whom he felt interested, from the pains of purgatory. Such indulgences were first invented in the eleventh century, by Urban II., as a recompense for those who went in person upon the glorious enterprize of conquering the Holy Land. They were afterwards granted to those who hired a soldier for that purpose; and in process of time were bestowed on such as gave money for accomplishing any pious work enjoined by the pope.

The power of granting indulgences has been greatly abused in the church of Rome. Leo X., in order to carry on the magnificent structure of St Peter's at Rome, published indulgences, and a plenary remission, to all such as should contribute money towards it. Finding the project take, he granted to Albert, elector of Mentz and archbishop of Magdeburg, the benefit of the indulgences of Saxony and the neighbouring parts, and farmed out those of other countries to the highest bidders, who, in order to make the most of their bargain, procured the ablest preachers to cry up the value of the commodity. The form of these indulgences was as follows: "May our Lord Jesus Christ have mercy upon thee, and absolve thee by the merits of his most holy passion. And I, by his authority, that of his blessed apostles Peter and Paul, and of the most holy Pope, granted and committed to me in these parts, do absolve thee, first from all ecclesiastical censures, in whatever manner they have been incurred; then from all thy sins, transgressions, and excesses, how enormous soever these may be, even from such as are reserved for the cognizance of the holy see, and as far as the keys of the holy church extend: I remit to you all punishment which you deserve in purgatory on their account; and I restore you to the holy sacraments of the church, to the unity of the faithful, and to that innocence and purity which you possessed at baptism; so that when you die, the gates of punishment shall be shut, and the gates of the paradise of delight shall be opened: and if you shall not die at present, this grace shall remain in full force when you are at the point of death. In the name of the Father, and of the Son, and of the Holy Ghost."

The terms in which the retailers of indulgences described their benefits and the necessity of purchasing them, were so extravagant, that they appear almost incredible. If any man, said they, shall purchase letters of indulgence, his soul may rest secure with respect to its salvation. The souls confined in purgatory, for whose redemption indulgences were purchased, as soon as the money tinkled in the chest, instantly escaped from that place of torment, and ascended into heaven. They maintained that the efficacy of indulgences was so great, that the most heinous sins would be remitted and expiated by them, and the person freed from both guilt and punishment; that this was the unspeakable gift of God, in order to reconcile man to himself; and that the cross erected by the preachers of indulgences was equally efficacious with the cross of Christ itself.

It was this great abuse of indulgences which mainly contributed to the reformation of religion in Germany, where Martin Luther began to declaim first against the preachers of indulgences, and afterwards against indulgences themselves; but since that time the popes have become much more sparing in the exercise of this power.

INDULT, in the church of Rome, the power of presenting to benefices granted to certain persons by the pope. Of this kind is the indult of kings and sovereign princes in the Roman Catholic communion, and that of the parliament of Paris granted by several popes. By the concordat for the abolition of the pragmatic sanction, made between Francis I. and Leo X. in 1516, the French king had the power of nominating to bishoprics, and other consistorial benefices within his realm. At the same time, by a particular bull, the pope granted to him the privilege of nominating to the churches of Bretagne and Provence. In 1648 Pope Alexander VIII., and in 1668 Clement IX., granted the king an indult for the bishoprics of Metz, Toul, and Verdun, which had been yielded to him by the treaty of Munster; and in 1668 the same Pope Clement IX. granted him an indult for the benefices in the counties of Rousillon, Artois, and the Netherlands. The cardinals likewise have an indult granted them by agreement between Pope Paul IV. and the sacred college in 1555, which is always confirmed by the popes at the time of their election. By this treaty the cardinals have the free disposal of all the benefices depending on them, and are empowered likewise to bestow a benefice *in commendam*.

INDULTO, a duty, tax, or custom, paid to the king of Spain on all such commodities as are imported from the West Indies in the galleons.

INDUS, also called the Nilab and the Sinde. This great river has its rise in the mountains of Tartary, lying between the 38 and 39 degrees of N. Lat., and is formed by two great branches, which join at the town of Dras, about 100 miles N.E. from Cashmeer. The left of these branches is seventy yards broad a little above the junction, and excessively rapid; it comes from the north of east, and runs west after being joined by the branch which passes the city of Lechdack in Thibet. According to information given to Mr Elphinstone by a Cashmerian, these head branches of the Indus joined about twenty-four miles above Dras, and at or below that town, the river divided into two branches, the lesser one running south to Cashmeer, but the greater one he knew little about, excepting that it was called the great Sinde. After passing the city of Lechdack in Thibet, it takes a south-westerly course, and forcing its way through the mountains called the Hindoo Coosh, it enters Hindostan about Lat. 33° 15′ N. Here, about sixty miles from its source, it is joined by the Cabul or Attock from the west; and it increases both in breadth and in depth, being about three-quarters of a mile in breadth in the month of July, and no longer fordable. Forty miles above

Indus.

the fort of Attock east-north-east, it is confined between high mountains as far as Torbela, where it enters the valley of Chuch, spreading and forming innumerable islands till it reaches the fort of Attock, where it again enters between the hills. At the fort it is only 260 yards broad, and both deep and rapid. It enters a plain five miles south of Attock, and is again confined between hills at Nilah, ten miles south of Attock, and continues to wind amongst deep groups of mountains on to Harrabah, latitude 33° 7′, where it enters the rich valley of the Esa Khels in four great branches, and is not again interrupted in its course by hills. From this point to where it is joined by the fine rivers of the Punjab, and flows in one stream, its course is south-east; and it enters the province of Sinde between the 25th and 26th degrees of N. Lat. Mr Elphinstone crossed the Indus in lat. 31° 28′ in January 1809, when the stream was at the lowest, and found its breadth to be 1905 yards. The depth of the channel at its deepest part was not above twelve feet; and an elephant ten and a half feet in height, had not a hundred yards to swim; the main channel being here reduced by several large branches which separate from it, and run in a parallel course, one 200 yards, another 500 yards, and a third 50 yards broad. Major Rennell estimates the delta of the Indus to be about 150 miles in length along the sea-coast; and about 115 in depth, from the place of separation of the superior branches of the river, to the most prominent point of the sea-coast. There is here water for vessels of nearly 200 tons burden, from the Gulf of Cutch to Lahore, a distance of 760 geographical miles. About 170 miles from the sea, by the course of the river, the Indus divides into two branches, of which the westernmost is by much the larger; and, after a course of about fifty miles to the south-west, as it approaches the sea, it is again subdivided into several other branches and creeks. The lower part of the delta is intersected by rivers and creeks in almost every direction, like the delta of the Ganges; but it so far differs from the latter, that it has no trees on its surface, the dry parts being covered with brushwood, and the remainder, by much the largest part, being noisome swamps or muddy lakes. It is remarkable that the influence of the tides is not felt at a greater distance than sixty or sixty-five miles from the sea. At the mouths of the different branches, the rush or influx of the tide is high and dangerous, running, as has been estimated, at the rate of four miles an hour, though varying greatly at different places. From the sea up to Hyderabad, the Indus is in general about a mile in breadth, varying in depth from two to five fathoms. The river begins to swell in the middle of July, from the melting of the snows, and continues to increase until the end of August. The length of the Indus is estimated by Mr Elphinstone, on the best data that he could collect, to be from Lechdack to Rodack, a place where wool is brought, or sheep, through a hilly country, to Cashmeer, to be manufactured into shawls, 250 miles; thence to the fort of Attock, 400 miles; and 700 to the sea; in all 1350 miles.[1] The Indus admits of an uninterrupted navigation from Tatta, the capital of Sinde, to Moultan and Lahore, for vessels of 200 tons, and a very extensive trade was carried on between these places in the time of Aurungzebe; and it is mentioned by Mr Burnes, in his visit to the Court of Sinde in 1828, that above Bunosa, which is thirty miles below Hyderabad, the river is nearly a mile broad, studded with boats, filling its channel from bank to bank, and moving majestically forward, at the rate of about three miles an hour.[2] But the trade has been frequently interrupted by the disorderly state of the country, owing to the bad government of Sinde, and the predatory incursions of the Sikhs and petty chiefs, who possess the countries of Moultan and Lahore, or the banditti who live under their precarious authority. The upper part of the delta is well cultivated, yielding abundance of rice,[3] and Mr Burnes, in his journey across it from Cutch, describes the extensive cultivation and richness of the soil from Buree to Toorta, as every where remarkable. He had every where to cross a number of canals dug for the purposes of agriculture, from the branches of the Indus, and over many of which small brick bridges were thrown, on which draw-wells were constantly at work irrigating the fields; and he observed a strong contrast between the parched deserts of Cutch and the exuberance of vegetable life exhibited in the delta of the Indus. This great river is named the Sindhis or Sindhus in Sanscrit, and Aub Sinde, or the water of Sinde, by the Persians. It is called by the natives Attock, from that place downwards to Moultan, and farther down to Soor or Shoor, until it separates in the Delta. The Asiatics generally distinguish it by the name of Sinde. It forms a strong barrier on the west of Hindostan for nearly 900 miles, and, if the country were resolutely defended, it would be a formidable obstacle to an invading army. The bed of the Indus is sand, with a small quantity of mud, and the water is wholesome, and quite fresh. Mr Burnes estimates that the Indus pours into the sea about four times as much water as the Ganges.

Inebriants | Infalistacio.

INEBRIANTS, are defined to be such things as affect the nerves in a particular and agreeable manner, and through them alter and disturb the functions of the mind. They are properly divided into natural and artificial; the former being chiefly in use amongst the oriental and other nations, the latter principally amongst those of Europe.

Natural Inebriants, are, 1. Opium, which is in use all over the East; 2. *Peganum harmala*, or Syrian rue, the seeds of which are sold in Turkey for this purpose; 3. Maslac of the Turks, or bangue of the Persians, prepared from the dust of the male-flower of hemp, or from the leaves; 4. Bangue of the Indians, from the leaves of the *Hibiscus sabdarissa;* 5. Seeds of various species of the datura, or thorn-apple; 6. Pinang, or betel of the Indians; 7. Roots of black henbane; 8. The *Hyoscyamus physaloides;* 9. Berries of the deadly nightshade; 10. Leaves of milfoil, used by the Dalekarlians to render their beer intoxicating; 11. Tobacco, and several others less material, such as clary, saffron, and darnel.

Artificial Inebriants, are fermented liquors from farinaceous seeds; and wines and spirits drawn by distillation. With these are ranked the nectar of the gods, and the anodyne medicine of Homer, commonly called *nepenthe.*

INERTIA *of* MATTER is defined by Sir Isaac Newton to be a passive principle by which bodies persist in a state of motion or of rest, receive motion in proportion to the force impressing it, and resist as much as they are resisted. It is also defined by the same author to be a power implanted in all matter, whereby it resists any change endeavoured to be made in its state. See PHYSICS.

IN ESSE is applied to things which are actually existing. Authors make a difference between a thing *in esse*, and a thing *in posse.* A thing that is not, but may be, they say is *in posse*, or *potentia;* but a thing apparent and visible, they say is *in esse*, that is, it has a real being *eo instanti*, whereas the other is casual, and at best but a possibility.

INFALISTACIO, an ancient punishment of felons, by throwing them amongst the rocks and sands, and chiefly used in port-towns. It is the opinion of some writers, that *infalistatus* implied some capital punishment, by exposing the malefactor upon the sand till the next tide carried him

[1] Elphinstone's *Account of the Kingdom of Cabul.* Appendix, p. 653.

[3] Burnes, *Narrative of a Visit to the Court of Sinde*, p. 40.

away; and of this custom, it is said, there exists an old tradition. However, the penalty seems to have taken its name from the Norman *falese*, or *falesia*, which signified not the sands, but the rocks and cliffs adjoining, or impending over the sea-shore. *Commisit feloniam ob quam fuit suspensus, ut legatus vel alio modo morti damnatus, ... vel apud Dover* infalistatus, *apud Southampton submersus.*

INFALLIBLE, that which cannot err, or be deceived. One of the great controversies between the Protestants and Catholics, is the infallibility which the latter attribute to the pope; though, in fact, they are not themselves agreed on that head, some placing this pretended infallibility in the pope and a general council, and others in his Holiness alone.

INFAMY, in *Law*, is that consequence of conviction for certain crimes, by which the person convicted incurs the *infamia juris*, and is thus rendered incapable of being a witness or juror, even though he be pardoned for his crime.

INFANCY, the first part of life. Hoffman says, that the human species are *infants* until they begin to talk, and *children* till the age of puberty. Anatomy discovers to us, that during infancy there is much imperfection in the human frame; its parts, for instance, are disproportioned, and its organs incapable of those functions which in future life they are designed to perform. The head is larger in proportion to the bulk of the body than that of an adult. The liver and pancreas are much larger in proportion than in advanced life; and their secretions are also more in quantity. The bile is very inert; the heart is stronger and larger than in future life; and the quantity of blood sent through the heart of an infant, in a given time, is also more in proportion than in adults. Though these circumstances have their usefulness, yet the imperfection attending them subjects this age to many injuries and dangers from which a more perfect state is exempt. Dr Percival observes, in his Essays, that of all the children who are born alive, two-thirds do not live to be two years old.

Infants have a larger proportion of brain than adults, and hence are most subject to nervous disorders; whilst the diagnostics of disease are in many respects obscure or uncertain, particularly those taken from the pulse, which, from the irritability of the tender bodies of infants, is suddenly affected by a variety of accidents too numerous, and seemingly too trivial, to gain our attention. From this cause, however, no very great embarrassment arises to the practitioner; for the disorders in this state are generally acute, less complicated than those in adults, and more easily discovered than is generally apprehended.

INFANTS, amongst the Jews, Greeks, and Romans, were swaddled as soon as they were born, in a manner similar to that practised by the moderns. The Jews circumcised and named their infant children on the eighth day from the birth. On the birth of a son, the Grecians crowned their doors with olives, on that of a daughter with wool. The infant was washed in warm water, and anointed with oil, and by the Spartans with wine; it was then dressed, and laid in a basket, or on a shield if the father was a warrior, particularly amongst the Spartans. At five days old they ran with it round the fire, and the mother's relations sent presents. The Greeks named their children on the tenth day, the Romans on the ninth; and this was attended with sacrifices and other demonstrations of joy.

INFANT, in *Law*, is a person under twenty-one years of age, whose capacities, incapacities, and privileges are various.

INFANTE, and INFANTA, all the sons and daughters of the kings of Spain and Portugal, except the eldest; the princes being called *infantes*, and the princesses *infantas*.

INFANTRY, in military affairs, the whole body of foot soldiers, whether consisting of independent companies or regiments. This word takes its origin from one of the infantas of Spain, who, finding that tne army commanded by the king her father had been defeated by the Moors, assembled a body of foot-soldiers, and with them engaged and totally routed the enemy. In memory of this event, and to distingush the foot-soldiers, who were not before held in much consideration, they received the name of *infantry*.

Heavy-armed INFANTRY, amongst the ancients, were such as wore a complete suit of armour, and engaged with broad shields and long spears. They formed the flower and strength of the Grecian armies. See ARMY.

Light-armed INFANTRY, amongst the ancients, were designed for skirmishing, and for fighting at a distance. Their weapons were arrows, darts, or slings.

Light INFANTRY, amongst the moderns, have only been in use since the year 1656. They have no camp equipage to carry, and their arms and accoutrements are lighter than those of the infantry. See ARMY.

INFATUATE, to prepossess any one in favour of some person or thing that does not deserve it, so that he cannot easily be disabused. The word comes from the Latin *fatuus*, fool; from *fari*, to speak out, which is borrowed from the Greek φαω, whence φατης, which signifies the same with *vates* in Latin, or *prophet* in English; and the reason is, because their prophets or priests used to be seized with a kind of madness, when they began to give out their predictions, or deliver oracles.

The Romans called those persons *infatuati*, who fancied that they had seen visions, or imagined that the god Faunus, whom they called *Fatuus*, had appeared to them. This word is more generally applied by the moderns to persons who are what the vulgar call *bewitched*, or under some peculiar destiny which it appears impossible for them to evade or escape.

INFEFTMENT, in *Scotch Law*, the symbolical surrender of an heritable subject to the purchaser, by delivering to him, in presence of witnesses, a small quantity of earth and stone of the property surrendered. It also denotes the writings which give effect to that ceremony.

INFERIÆ, sacrifices offered by the Romans to the *Dii Manes*, or the souls of deceased heroes or other illustrious persons, or even any relation or person whose memory was held in veneration. These sacrifices consisted of honey, water, wine, milk, the blood of victims, a variety of balsamic unguents, chaplets, and loose flowers. The victims upon these occasions were generally of the smaller cattle, though in ancient times they sacrificed slaves or captives. The sacrifices were usually black and barren. The altars upon which they were offered were holes dug in the ground.

The honey, water, wine, milk, and blood, were used as libations, and were poured upon the tombs of children by children, upon those of virgins by virgins, and upon those of married men by women. The *inferiæ* were offered on the ninth and thirtieth days after interment amongst the Greeks, and repeated in the month Anthesterion. The whole of this article applies equally to the Greeks and the Romans.

INFIBULATION, in antiquity. It was a custom amongst the Romans to infibulate their singing boys, in order to preserve their voices; for this operation, which is the very reverse of circumcision, kept them from injuring their voices by premature venery.

INFIDEL, a term applied to such persons as are not baptized, and do not believe in the truths of the Christian religion.

INFIDELITY, in a general sense, denotes want of faith or belief in regard to any subject or transaction. *Religious Infidelity* signifies a disbelief of Christianity.

"Of all the methods," says Dr Knox, "which the vanity of man has devised with a view to acquire distinction, there is none easier than that of professing a disbelief of the established religion. That which shocks the feelings of those with whom we converse, cannot fail of attracting notice; and as the vain are usually confident, they utter their doubts with an air so oracular and decisive, as induces the simple to think them profoundly wise. Audacity, with little ingenuity, will attract the eyes of spectators, and this will sufficiently answer the purpose of many amongst the professed unbelievers. One might be diverted, if one were not hurt, at seeing a circle of silly admirers, gaping and fixing their eyes on some half-learned and impudent prater, who throws out oblique insinuations against the Bible, the clergy, or the sacrament. These are fertile topics of wit and ingenuity; but it might mortify the vanity of some very vain writers and talkers, if they were to recollect, what is undoubtedly true, that it is a species of wit and ingenuity which not only the vilest, but the most stupid and illiterate of mankind, have frequently displayed in all its possible perfection.

" There is indeed no doubt, but that vanity is one of the principal causes of infidelity. It must be the sole cause of communicating it to others, by writing or conversation. For let us suppose the case of a very humane, judicious, and learned man, entertaining doubts of the truth of Christianity: If he cannot clear his doubts by examination, he will yet recollect that doubts are no certainties; and, before he endeavours to propagate his scepticism, he will ask himself these questions: ' Am I quite convinced that what I doubt of cannot possibly be true? If I am convinced of it, am I sure that the publication of my opinions will not do more harm than good? Is not the disturbing of any long-established civil constitution attended with confusion, rebellion, bloodshed, and ruin? And are not the majority of men more strongly attached to the religion than the government of their forefathers? Will it serve my country to introduce discontent of any species? May not those innovations in religion, which discontent may introduce, lead to all the evils which are caused by frenzy and fanaticism? Granting that I were able to make a party formidable enough to crush opposition and to exterminate Christianity, still am I certain that I act, in this instance, like a good member of society? For is not this system, whether well or ill founded, friendly to society? I must confess it; its greatest enemies have acknowledged it. What motive, then, can induce me to divulge my doubts of its authenticity? Not the good of mankind; for it is already allowed by unbelievers, that the good of mankind is interested in the belief of its divine original. Is it for my own good, and with a view to be convinced? I will not deceive myself: my motive, I suspect, is of another kind; for do I read those books which have been already written to satisfy similar doubts? Nothing but the vanity of appearing to be wiser than my credulous neighbours can induce me to interrupt the happiness of their belief. But vanity of this sort, which tends to disturb society, to injure the national morals, and to rob many thousand individuals of a copious source of sweet and solid comfort, must be pronounced extreme wickedness, even according to the obvious dictates of natural religion. I shall act the part of a good citizen and a good man, by conforming to a system whose beneficial influence I feel and confess, and by endeavouring to acquire a belief in that which has for so many centuries been established, and which promises to soothe me in distress with the sweetest consolations, and to brighten the dismal hour of death, by the hope of a more glorious and happy state of existence. At all events, I shall have the satisfaction of having commanded myself so far, as not to have run the hazard of endangering the welfare of my fellow-creatures, either here or hereafter, by indulging a degree of vanity, which, in a creature so weak and so short-lived as myself, is a folly very inconsistent with the superior wisdom which I seem to arrogate."

" I will venture to repeat," continues our author, " that all writers against Christianity, however they may affect even the extremes of benevolence, honour, philosophy, and enlargement of mind, are actuated by vanity and wickedness of heart. Their motives are as mean, selfish, narrow, and in every respect unjustifiable, as the tendency of their writings is mischievous. Their malice is often impotent, through the foolish sophistry of their arguments; but, if ever it be successful, it is highly injurious: and, indeed, considering their motives, and the probable consequences of their endeavours, the infidel writer is a greater enemy to society, and consequently guiltier, according to all the principles of social union, than the thief or the traitor. Persecution would, however, only promote his cause, and his proper punishment is contempt.

" It is certainly no derogation from the character of a man of sense, to conform, even while he is so unfortunate as to doubt their truth, to the opinions of his country. His conformity will probably lead him to a train of actions and of thought, which, in due time, will induce him to believe. But, if that should not happen, yet he will act, as very wise and very great men have acted, in paying a respectful deference to the avowed conviction of others. The most intelligent and powerful men of ancient Rome, not only appeared to believe a very absurd and hurtful system, but assisted in all its ceremonies as priests. Even Socrates, who evidently entertained some notions adequate to the dignity of the one great and supreme Being, yet thought it was a duty which he owed to his country, so far to conform to the wretched establishment, as to order in his dying words a sacrifice to Æsculapius. This external conformity to the national religion ought not to be confounded with hypocrisy. If, indeed, it is carried to extremes, or zealously affected, it certainly is very blameable and contemptible deceit; but while it keeps within the bounds of reason and moderation, it ought to be called a decent deference to the opinions of the majority, arising from humility, and from a desire to maintain the tranquillity of the state, and to continue an innocent and useful system, which has, and will always greatly contribute to lessen the quantity and degree both of moral and of natural evil.

" The easiest, after all, or at least the most effectual method of appearing in any character, is really to be what we wish to appear. But belief, you will say, is not in our power, and how can we believe what appears to us incredible? Certainly you cannot while it appears incredible. But let me ask you, whether you have taken any pains to believe, or have at once and at a glance persuaded yourself, that the Christian religion is totally false? It is probable that a great number of sceptical writers never gave themselves the trouble to read those Scriptures which they warmly oppose. They hear objections, they read objections, and they find, that from men of reputed wit and ingenuity the objections often originate. They also wish to be reputed men of wit and ingenuity, and therefore eagerly adopt the language and sentiments of the order. Perhaps the vanity and pride of this class of men will render all attempts to convince them abortive; but to modest doubters, and to those whose good sense and good dispositions lead them to wish to adopt the religion of their country, it may not be useless to suggest advice, with a view to facilitate their conviction.

" The chief thing required is to free themselves from the pride of human reason. Humility (and surely our blindness and imperfections are sufficient to render us humble, if we would be reasonable), humility will open our hearts, and belief will find admission. Sincere endeavours, seconded by prayers, will never fail to help our unbelief. But, alas! a fine, gay, spirited, liberal, and enlarged modern philosopher, would be ashamed to be found on his knees, or with a Testament in his possession. There is scarcely any vicious act, or any vicious book, which would put him so much to the blush.

"A modest well-meaning man might, however, one should think, divest himself of those prejudices which prevent the possibility of belief, by the following soliloquy:—I find myself placed in a world abounding with evil and misery. Under the immediate pressure of it, I feel my heart inclining, like the needle to the north, by its natural tendency, to the Deity for support. Man, of all animals, is the only one who has the sense of religion. Feeling this distinctive propensity of my nature, I look around to discover to what object, and in what manner, that part of my fellow creatures, who live in the same society with myself, pay their adoration. I find a system of religion already established, and which has been established in the most enlightened countries of the earth near two thousand years. I resolve to examine it. It claims that respect from its antiquity and universality. Many difficulties appear on the first inspection. My reason is often startled, and my belief wavers. But I will not yet give up a point of so serious importance, without further and closer attention to it. I reflect, that two thousand years is a vast space in the age of the world. How many myriads of men like myself have lived and died in the faith during that time. And were all of them fools or hypocrites? It could not have been. Can the understanding of a poor individual, just come into the world, and hardly knowing where he is, comprehend on intuition an object of such magnitude, and make the mighty discovery which has escaped millions of the wisest and most learned of mortals? Or, supposing that they all perceived the deception, am I then at last the only honest man who will confess it? I am ashamed to avow such an idea to myself. But yet, if I reject what they received, surely I avow it in the more expressive language of my conduct. Pride, I fear, is the foundation of my scepticism, and humility must form the basis of my belief. I will check my own presumption, and reject the cavils of vain and foolish philosophy. Shall a poor weak creature, who cometh up like a flower, and is cut down, who fleeth as a shadow, and never continueth in one stay, presume to pronounce decisively in that little period, in which he has scarcely time to look about him before he dies, against a system which has strong internal and external evidence of divine original, which is most useful and comfortable, and which has been admitted among a great portion of mankind during almost twenty centuries? No, it is the first wisdom to be humble. Humility will be followed by grace, and grace by faith, and faith by salvation. It plainly appears, that I can lose nothing by belief, but some of those excessive and irregular enjoyments which would destroy my health and life; but I may possibly gain a glory and a happiness which shall continue to all eternity."

INFINITE, that which has neither beginning nor end; in which sense God alone is infinite.

INFINITE is also used to signify that which has had a beginning, but will have no end, as angels and human souls. This makes what the schoolmen call *infinitum a parte post;* as, on the contrary, by *infinitum a parte ante,* they mean that which has an end, but had no beginning.

INFINITE Quantities. The very idea of magnitudes infinitely great, or such as exceed any assignable quantities, includes a negation of limits; yet if we examine this notion, we shall find that such magnitudes are not equal amongst themselves, but that there are really, besides infinite length and infinite area, three several sorts of infinite solidity, all of which are *quantitates sui generis,* and that those of each species are in given proportions.

Infinite length, or a line infinitely long, is to be considered either as beginning at a point, and so infinitely extended one way, or else both ways from the same point; in which case the one, which is a beginning infinity, is the one-half of the whole, which is the sum of the beginning and ceasing infinity; or, as may be said, of infinity *a parte ante* and *a parte post,* which is analogous to eternity in time and duration, in which there is always as much to follow as is past, from any point or moment of time; nor does the addition or subtraction of finite length, or space of time, alter the case either in infinity or eternity, since both the one or the other cannot be any part of the whole.

INFINITESIMALS, amongst mathematicians, are defined to be infinitely small quantities.

In the method of infinitesimals, the element, by which any quantity increases or decreases, is supposed to be infinitely small, and is generally expressed by two or more terms, some of which are infinitely less than the rest; and this being neglected as of no importance, the remaining terms form what is called the *difference of the proposed quantity.* The terms which are neglected in this manner, as infinitely less than the other terms of the element, are the very same which arise in consequence of the acceleration or retardation of the generating motion, during the infinitely small time in which the element is generated; so that the remaining terms express the elements which would have been produced in that time, if the generating motion had continued uniform; and therefore those differences are accurately in the same ratio to each other as the generating motions or fluxions. Hence, though in this method infinitesimal parts of the elements are neglected, the conclusions are accurately true without even an infinitely small error, and agree precisely with those which are deduced by the method by fluxions. See FLUXIONS.

INFINITIVE, in *Grammar,* the name of one of the moods, and so called in contradistinction to those that are finite. See GRAMMAR.

INFINITY, the quality which renders a thing infinite.

INFIRMARY, a kind of hospital, where the weak and sick are properly taken care of.

INFLAMMABILITY, that property of bodies which disposes them to kindle or catch fire. See CHEMISTRY.

INFLATION (formed from *in* and *flatus* from *flo,* I blow), blowing up, the act of stretching or filling any flaccid or distensible body with a flatulent or windy substance.

INFLECTION, called also *diffraction,* and *deflection,* in *Optics,* is a property of light, by reason of which, when it comes within a certain distance of any body, it is either bent from it, or towards it; which is a kind of imperfect reflection or refraction. See OPTICS.

INFLECTION, or *Point of INFLECTION,* in the higher geometry, is a point where a curve begins to bend in a contrary way.

INFLECTION, in *Grammar,* the variation of nouns and verbs, by declension and conjugation.

INFORMATION, in *Law,* is nearly the same in the crown office as that which in other courts is called a *declaration.* Informations are of two sorts; first, those which are partly at the suit of the king, and partly at that of a subject; and, secondly, such as are only in the name of the king.

INFORMER (*informator*) in *Law,* a person who informs against, or prosecutes in any of the king's courts, those that offend against any law or penal statute.

Informers were very common both in Greece and in Rome. Every corner of the streets was infested with persons who made it their constant business to pick up stories, and catch at every occasion to accuse persons of credit and reputation. These persons were called by the Greeks Συκοφανται; for a more particular account of whom see SYCOPHANT.

Amongst the Romans, informers were of two sorts, *mandatores* and *delatores.* These played into each other's hands; the former marking down such persons as they pretended to have found guilty of any misdemeanour, and the latter prosecuting them. What tended to increase the number of these pestilent wretches was, that the informers were entitled to a fourth part of the effects of the person convicted. Wicked princes rewarded and countenanced this mischievous tribe; but Titus set on foot a most diligent search after them, and punished such as he found with death or banishment. Trajan also is praised by Pliny for pursuing similar conduct.

INFRACTION (formed from *in*, and *frango*, "I break"), a rupture or violation of a treaty, law, ordinance, or the like.

INFRALAPSARII, the name of a sect of predestinarians, who maintain, that God has created a certain number of men only to be damned, without allowing them the means necessary to save themselves, if they would; and they are thus called, because they hold that God's decrees were formed *infra lapsum*, after his knowledge of the fall, and in consequence thereof. The Infralapsarians are contradistinguished from the SUPRALAPSARIANS.

INFULA, in antiquity, was a mitre worn upon the head by the Grecian and Roman priests, and from which on each side hung a riband. The covering of the head with a mitre was rather a Roman than a Grecian custom, introduced into Italy by Æneas, who covered his head and face at the performance of sacrifice, lest any ill-boding omen should disturb the rites. The *infulæ* were commonly made of wool, and were not only worn by the priests, but were put upon the horns of the victims, upon the altar and the temple. The *infulæ* were also called *vittæ*.

INFUSION, in *Pharmacy*, an operation, by which the virtues of plants are drawn out, by steeping them in some convenient fluid without boiling.

INGATESTONE, a town of the county of Essex, on the hundred of Chelmsford, twenty-three miles from London. In the church are several fine monuments of the noble family of Petre, whose residence is here. There is an endowed classical school. The inhabitants amounted in 1801 to 645, in 1811 to 640, in 1821 to 747, and in 1831 to 789.

INGELMUNSTER, a large town of the Netherlands, in the province of Courtray. It stands on the river Mandelbeke, on the great road from Bruges to Courtray, and contains 5350 inhabitants, chiefly occupied in making linen goods and fine thread-lace.

INGENHOUSZ, JOHN, an eminent physician and natural philosopher, was born at Breda in 1730. He was first established in medical practice there, but removed to London in 1767, particularly with a view to study the improved methods of inoculation then recently introduced. Having become acquainted with Sir John Pringle, at that time President of the Royal Society, he was by him recommended to the Austrian ambassador, for the purpose of inoculating the Imperial family at Vienna, the Empress Maria Theresa having lost two of her children by the natural small-pox. He accepted this engagement in 1768, and having been perfectly successful in his operations, he was remunerated by the grant of a pension of L.600 a-year for life, together with the titles of Aulic Counsellor and Physician to the Imperial Family. He was also consulted, in his medical capacity, by many others of the most distinguished personages at Vienna, and he enjoyed the particular esteem of the Emperor Joseph II., who was fond of receiving him in his cabinet, and of witnessing the exhibition of a variety of physical experiments, with which it was always the delight of Ingenhousz to amuse and instruct his acquaintance of both sexes. The following spring he went to Italy, and inoculated the Grand Duke of Tuscany. He was made a Fellow of the Royal Society in May 1769; but he appears to have remained some years in Italy, for he was at Leghorn in January 1773; in March he dates from Salzburg; and in November 1775 from Vienna. The next year he was in London; and, in the winter of 1779, he went to Paris. The latter part of his life he spent principally in England, which, notwithstanding his dislike to the chillness of the climate, was always his favourite residence, and "where he enjoyed during many years," to use his own words, "that felicity which a free and independent man finds in the pursuit of knowledge and wisdom, in the society and friendly intercourse of those who have distinguished themselves by their learning."

Dr Ingenhousz was cheerful in his disposition, and often playful in his conversation. Though his pursuits were chiefly scientific, he was not destitute of taste for literature and poetry. He had a particular predilection for Lucan, and for the Cardinal de Polignac, and would frequently recite passages from their poems with great energy, and with a strong German accent. Nor did he disdain the comforts of commercial opulence, and he was often a visitor at the magnificent villa of the late Mr Rucker of Rohampton. He had been introduced there by his friend Dr Brocklesby, who was in many respects of a perfectly congenial disposition, and who had great pleasure in prevailing on him to partake occasionally of his own hospitality, when his table would otherwise have been solitary. He died the 7th September 1799, at Bow Wood, in Wiltshire, the house of the Marquis of Lansdown, who had long known and esteemed him.

Dr Ingenhousz's principal publications are, 1. *Experiments on the Torpedo. Phil. Trans.* 1775, p. 1. Mr Walsh had lately gained considerable reputation by his account of the effects of the torpedo. These experiments, which were made off Leghorn, in company with Dr Drummond, are merely illustrative of the properties of that animal, which are now better known; and they afford no decided test of the electrical nature of the phenomena.

2. *Methods of Measuring the Bulk of Mixtures of Common Air, and Nitrous Air, with Experiments on Platina. Phil. Trans.* 1776, p. 257. The eudiometrical apparatus is described as an improvement on Fontana's. The experiments are intended to shew that platina is not an alloy of iron and gold, since it may be deprived of all magnetic properties by repeated cupellation.

3. *A Way of Lighting a Candle by an Electrical Spark. Phil. Trans.* 1778, p. 1022. A very small charged jar setting fire to pulverised resin, strewed on cotton.

4. *On the Electrophorus*, p. 1027. This is a Bakerian lecture, read by appointment of the President and Council of the Royal Society, relating to the instrument then lately invented by Professor Volta, and which had been made known to the author by the Archduke Ferdinand. Its action is explained upon the elementary principles of the Franklinian theory. The next article in the volume contains some experiments of Mr Henly in confirmation of the doctrines here advanced.

5. *On a New Inflammable Gas. Phil. Trans.* 1779, p. 576. A powerful explosion is produced by the detonation of the vapour of a single drop of ether with oxygen gas. The author takes occasion to investigate the elasticity of the gas evolved by the detonation of gunpowder; and agrees with Bernoulli in estimating it as equivalent to near 2500 atmospheres. It may here be remarked, that notwithstanding Bernoulli's general accuracy, and great mathematical talents, he has fallen into a very singular error, in comparing the force of gunpowder with the daily labour of men; and has accidentally made the force of one pound equivalent to the daily work of 100 men, while, in fact, the force of 40 pounds is only equivalent to the daily labour of a single man.

6. *On a Mode of Suspending Magnetical Needles*, p. 537. Proposing that a hollow needle should be immersed in linseed oil, so as to press with a small portion of its weight only on its axis, in order that the friction may be greatly diminished.

7. *Improvements in Electricity*, p. 661. On plate ma-

chines of glass and pasteboard, and on a riband machine. A Bakerian lecture.

8. *Experiments on Vegetables.* London, 1779. This volume is chiefly occupied by the detailed proofs of the author's principal discovery, that vegetables in general pour out a portion of oxygen gas in the sunshine, while they rather diminish its proportion at night and in the shade. It is dedicated to Sir John Pringle, and was translated into *French* by the author. Paris, 1786. Second edition, 2 vols. 8vo, 1787–9. *Latin by Scherer.* Vienna, 1786. *Dutch by Dr Van Breda,* of Delft, with others of his works.

9. *On the Salubrity of the Air at Sea, and at Places far removed from the Sea. Phil. Trans.* 1780, p. 554. From the imperfection of the test employed, it was easy to imagine that some differences were discovered, which subsequent observations have shewn to have no existence.

10. *Nouvelles Expériences et Observations,* 2 vols. 8vo. Paris. On different subjects of natural philosophy. In German by *Molitor, Vermischte Schriften.* Vienna, 1784.

11. *On the Influence of the Vegetable Kingdom in the Animal Creation. Phil. Trans.* 1782, p. 426. Asserting the accuracy of his experiments, and denying some statements of Dr Priestley; advancing, in particular, many arguments to prove that the air obtained is really supplied by the vegetables, and not by the water in which they are usually immersed, in order to collect it. Dr Ingenhousz was, on all occasions, anxious to support his claim to this very interesting discovery; and he insisted that Priestley's earlier experiments, on the green matter contained in stagnant water, had little or nothing in common with his own, because that matter was, in fact, of an animal nature. He was in the habit of collecting the gas from cabbage leaves, and of keeping it bottled up in his pocket; and he was prepared with some coils of iron wire fastened into the corks, in order to exhibit the brilliant phenomenon of their combustion to his friends; the public being at that time less accustomed to this dazzling exhibition, than it has become in later years, when elementary lectures on chemistry have been more commonly addressed to mixed audiences than heretofore.

12. *Essay on the Food of Plants,* 8vo. London, 1798. From the French.

13. Dr Ingenhousz also inserted some essays in different volumes of the *Journal de Physique;* but they possess less originality and importance than his English publications.

(Chalmers's *Biographical Dictionary,* xix. London, 1815, 8vo; Kesteloot in *Biographie Universelle,* xxi. Paris, 1818, 8vo.) (L. L.)

INGENUOUS, in a general sense, signifies *open, fair,* and *candid.*

Ingenuous (*ingenuus*), in Roman antiquity, an appellation given to persons born of free parents, who had never been slaves. The children of the *liberti,* or persons who had obtained their liberty, were called *libertini,* not *ingenui;* this appellation of *ingenuus* being reserved for their children, or the third generation.

INGERAM, a town of the south of India, in the northern circars, district of Rajamundry, five miles south from Corenga. Longitude 82° 25′ east, latitude 16° 46′ north.

INGESTA, is used by some authors to express all sorts of aliment taken into the body.

INGLIS Island, a long island on the north coast of New Holland, near the entrance into the Gulf of Carpentaria. It is on the west side of the gulf, and is twelve miles long, and from one to three miles in breadth.

INGLUVIES, the crop or craw of granivorous birds, serving for the immediate reception of the food, where it is macerated for some time before it is transmitted to the true stomach.

INGOLSTADT, a city of the kingdom of Bavaria in the circle of Regen, on the right bank of the Danube is one of those places which has declined by the loss of its woollen manufactures, which were formerly of great extent. It is now merely the seat of the courts of justice and revenue for the circle. It contains a royal palace, nine churches, an hospital and public school, and 745 houses, inhabited by 4820 persons. Latitude 48° 45′ 55″, longitude 11° 20′ 32″ east.

INGOT, a mass of gold or silver melted down, and cast in a mould, but not coined or wrought.

INGRAFTING. See Horticulture.

INGRATITUDE, the opposite of gratitude. Ingratitude is a crime so shameful, that there never was a man found who would own himself guilty of it; and, though too frequently practised, it is so abhorred by the general voice, that to be ungrateful is to be liable to the imputation of the guilt or the capability of committing all other crimes.

In a little work entitled *Friendly Cautions to Officers,* the following atrocious instance of ingratitude is related. An opulent city in the west of England, little used to have troops with them, had a regiment sent to be quartered there; and the principal inhabitants and wealthiest merchants, glad to shew their hospitality and attachment to their sovereign, took the first opportunity to get acquainted with the officers, inviting them to their houses, and shewing them every civility in their power. This was truly a desirable situation. A merchant, extremely easy in his circumstances, took so prodigious a liking to one officer in particular, that he gave him an apartment in his own house, and made him in a manner absolute master of it, the officer's friends being always welcome to his table. The merchant was a widower, and had only two favourite daughters; the officer, in so comfortable a station, cast his wanton eyes upon them; and too fatally succeeding, ruined both. The consequence of this ungenerous action was, that all officers were ever afterwards shunned as a public nuisance, and a pest to society; nor have the inhabitants perhaps yet conquered their aversion to a red-coat.

We are informed by Rapin, that during Monmouth's rebellion, in the reign of James II. a certain person knowing the humane disposition of one Mrs Gaunt, whose life had been one continued exercise of beneficence, fled to her house, where he was concealed and maintained for some time. Hearing, however, of the proclamation, which promised an indemnity and reward to those who discovered such as harboured the rebels, he betrayed his benefactress; and such was the spirit of justice and equity which prevailed amongst the ministers, that he was pardoned and recompensed for his treachery, whilst she was burned alive for her charity.

The following instance is also mentioned by the same author. Humphry Bannister and his father were both servants to and raised by the Duke of Buckingham, who being driven to abscond, by an unfortunate accident befalling the army he had raised against the usurper Richard III., retired, without footman or page, to Bannister's house near Shrewsbury, as to a place where he had all the reason in the world to expect security. Bannister, however, upon the king's proclamation, promising L. 1000 reward to him who should apprehend the duke, betrayed his master to John Merton, high sheriff of Shropshire, who sent him under a strong guard to Salisbury, where the king then was, and there in the market-place the duke was beheaded. But divine vengeance pursued the traitor Bannister; for demanding the L. 1000 which was the price of his master's blood, King Richard refused to pay it, saying, that "he who would be false to so good a master, ought not to be encouraged." He was afterwards hanged for manslaughter, his eldest son run mad and died in a hog-sty, his second became deformed and lame, and his third son was drowned in a small puddle of water. His eldest daughter was seduced by one of his own carters, and his second was seized with a leprosy of which she died.

The following barbarous instances are from ancient History. When Xerxes king of Persia was at Celene, a city of Phrygia, Pythius, a Lydian, who had his residence in that city, and next to Xerxes was the most opulent prince of those times, entertained him and his whole army with an incredible magnificence, and made him an offer of all his wealth towards defraying the expenses of his expedition. Xerxes, surprised and charmed at so generous an offer, had the curiosity to inquire to what sum his riches amounted. Pythius made answer, that having the design of offering them to his service, he had taken an exact account of them, and that the silver he had by him amounted to two thousand talents (about L. 255,000 Sterling), and the gold to four millions of darics (about L. 1,700,000 Sterling). All this money he offered him, telling him that his revenue was sufficient for the support of his household. Xerxes made him very hearty acknowledgments, and formed a particular friendship for him, but declined accepting his present. The same prince who had made such obliging offers to Xerxes, having desired a favour of him some time afterwards, that out of his five sons who served in his army, he would be pleased to leave him the eldest, in order to be a comfort to him in his old age, the king was so enraged at the proposal, though so reasonable in itself, that he caused the eldest son to be killed before the eyes of his father, giving the latter to understand, that it was a favour he spared him and the rest of his children. Yet this is the same Xerxes who is so much admired for his humane reflection at the head of his numerous army, " that of so many thousand men, in a hundred years time there would not be one remaining; on which account he could not forbear weeping at the uncertainty and instability of human things." He might have found another subject of reflection, which would have more justly merited his tears and affliction, had he turned his thoughts upon himself, and considered the reproaches he deserved for being the instrument of hastening the fatal term to millions of people, whom his cruel ambition was going to sacrifice in an unjust and unnecessary war.

Basilius Macedo the Emperor, exercising himself in hunting, a sport he took great delight in, a great stag running furiously against him, fastened one of the branches of his horns in the emperor's girdle, and pulling him from his horse, dragged him a good distance, to the imminent danger of his life; which a gentleman of his retinue perceiving, drew his sword and cut the emperor's girdle asunder, which disengaged him from the beast, with little or no hurt to his person. But observe what reward he had for his pains. " He was sentenced to lose his head for putting his sword so near the body of the emperor;" and suffered death accordingly.

INGRESS, in *Astronomy*, signifies the sun's entering the first scruple of one of the four cardinal signs, especially Aries.

INGROSSER, or ENGROSSER, in common law, is one who buys up corn growing, or any provisions by wholesale, before the market, to sell again. It also signifies a clerk who writes records or instruments of law on skins of parchment.

INGULPHUS, abbot of Croyland, and author of the history of that abbey, was born in London about the year 1030. He received the first part of his education at Westminster; and when he visited his father, who belonged to the court of Edward the Confessor, he was so fortunate as to engage the attention of Queen Elgitha. That amiable and learned princess took a pleasure in examining our young scholar on his progress in grammar, and in disputing with him in logic; nor did she ever dismiss him without some present as a mark of her approbation. From Westminster he went to Oxford, where he applied to the study of rhetoric, and the Aristotelian philosophy, in which he made greater proficiency than many of his contemporaries. When he was about twenty-one years of age, he was introduced to William Duke of Normandy, who visited the court of England in the year 1051, and made himself so agreeable to that prince, that he appointed him his secretary, and carried him with him into his own dominions. In a little time he became the prime favourite of his prince, and the dispenser of all preferments, humbling some, and exalting others, at his pleasure; a station in which he confessed he did not behave with a proper degree of modesty and prudence. This excited the envy and hatred of many of the courtiers; to avoid the effects of which, he obtained leave from the duke to undertake a pilgrimage to the Holy Land. With a company of thirty horsemen he joined Sigfrid Duke of Mentz, who, with many German nobles, bishops, clergy, and others, was preparing for a pilgrimage to Jerusalem. When they were all united, they formed a company of no fewer than seven thousand pilgrims. In their way they spent some time at Constantinople, performing their devotions in the several churches. In their passage through Lycia, they were attacked by a tribe of Arabs, who killed and wounded many of them, and plundered them of a prodigious amount of money. Those who escaped from this disaster at length reached Jerusalem, visited all the holy places, and bedewed the ruins of many churches with their tears, giving money for their reparation. They intended to have bathed in Jordan; but being prevented by the roving Arabs, they embarked on board a Genoese fleet at Joppa, and landed at Brundusium, whence they travelled through Apulia to Rome. Having gone through a long course of devotions in this city, at the several places distinguished for sanctity, they separated, and every one made the best of his way to his own country. When Ingulph and his company reached Normandy, they were reduced to twenty half-starved wretches, without money, clothes, or horses; the ordinary result of the disastrous journeys into the Holy Land, so common in those times. Ingulph was now so much disgusted with the world, that he resolved to forsake it, and became a monk in the abbey of Fontenelle in Normandy; in which, after some years, he was advanced to the office of prior. When his old master was preparing for his expedition into England in 1066, he was sent by his abbot a hundred merks in money, and twelve young men, nobly mounted and completely armed, as a present from the abbey. Ingulph having found a favourable opportunity, presented his men and money to his prince, who received him very graciously. In consequence of this, the Conqueror raised him, in 1076, to the government of the rich abbey of Croyland in Lincolnshire, where he spent the last thirty-four years of his life, governing that society with great prudence, and protecting their possessions from the rapacity of the neighbouring barons by the favour of his royal master. The lovers of English history and antiquities are much indebted to this learned abbot, for his excellent history of the abbey of Croyland, from its foundation in 664 till 1091, into which he has introduced much of the general history of the kingdom, with a variety of curious anecdotes which are nowhere else to be found. Ingulph died of the gout, at his abbey, in 1109, in the seventy-ninth year of his age. His history is printed in Gale's Collection of early English Historians. A separate edition was published at Oxford in the year 1684.

INHERITANCE, a perpetual right or interest in lands, invested in a person and his heirs.

INHIBITION, a writ to inhibit or forbid a judge from further proceeding in a cause depending before him.

In *Scotch Law*, it is a writ obtained at the suit of a creditor against his debtor, prohibiting him from selling or contracting debts upon his estate to the creditor's prejudice.

INJECTION, the forcibly throwing certain liquid medicines into the body by means of a syringe, tube, clyster-pipe, or the like.

INJECTION, in *Surgery*, the throwing in some liquor or medicine into a vein opened by incision. See SURGERY.

INISTIOGE, a post town of Kilkenny, in the province of Leinster. It is situated upon the Nore, at sixty-three miles distance from Dublin.

INITIATED, a term properly used in speaking of the religion of the ancient heathens, where it signifies being admitted to the participation of the sacred mysteries. The word comes from the Latin *initiatus*, from *initiare*, *initiari*, which properly signifies to begin sacrificing, or to receive or admit a person to the beginning of the mysteries, or of ceremonies of less importance.

The ancients never discovered the deeper mysteries of their religion, nor even permitted some of their temples to be opened, to any but those who had been initiated. See MYSTERY.

INJUNCTION, in *Law*, a writ generally grounded upon an interlocutory order or decree out of the Court of Chancery or Exchequer, sometimes to give possession to the plaintiff, for want of the defendant's appearance; sometimes to the King's Ordinary Court, and sometimes to the Court-Christian, to stop proceedings in a cause, upon suggestion made, that the rigour of the law, if it take place, will be against equity and conscience in that case, that the complainant is not able to make his defence in these courts, for want of witnesses, &c., or that they act erroneously, denying him some just advantage. The writ of injunction is directed not only to the party himself, but to all and singular his counsellors, attorneys, and solicitors; and if any attorney, after having been served with an injunction, proceeds afterwards contrary to it, the Court of Chancery will commit the attorney to the Fleet for contempt. But if an injunction be granted by the Court of Chancery in a criminal matter, the Court of King's Bench may break it, and protect any who proceed in contempt of it.

INK, a black liquor, used in writing. The name is also applied to liquids and pigments of various colours, used in printing as well as in writing. We shall notice these compounds in the following order, 1. Black Writing Ink, comprehending under this head the ordinary methods of composition recommended by chemists, the improvements which a more extended manufacture have effected, the methods suggested for rendering ink imperishable, and the inquiries which have been instituted into the composition of ancient inks, with the methods proposed for renewing faded writing; 2. Indian Pigment or Ink; 3. Red Ink; 4. Blue Ink; 5. Printing Ink; 6. Ink for the Rolling Press; 7. Lithographic Ink; 8. Sympathetic Ink.

Black Writing INK. The properties which this liquor ought to have, are, 1. To flow freely from the pen, and sink a little into the paper, that the writing may not be easily discharged; 2. a very deep black colour, which should be as deep at first as at any time afterwards; 3. durability, so that the writing may not be subject to decay by age; and 4. ink should be destitute of any corrosive quality, that it may not destroy the paper, or go through it in such a manner as to render the writing illegible.

In Mr Delaval's *Treatise on Colours*, (p. 37), he acquaints us, that with an infusion of galls and iron filings, he had not only made an exceedingly black and durable ink, but by its means, without addition of any acid, dyed silk and woollen cloth of a good and lasting black. This kind of ink, however, though the colour is far superior to that of any other, has the inconvenience of being very easily discharged, either by the smallest quantity of any acid, or even by simple water; because it does not penetrate the paper in such a manner as is necessary to preserve it from the instantaneous action of the acid or of the water. During the action of the infusion of galls upon the iron in making this kind of ink, a very considerable effervescence takes place, and a quantity of air is discharged, the nature of which has not yet been examined.

The materials usually employed for the making of ink are, common green vitriol, or copperas, and galls; but almost all of them are deficient in durability, which is a property of such importance, that Dr Lewis thought the subject of ink-making not unworthy of his attention. From experiments made by that author, he infers, that the decay of inks is chiefly owing to a deficiency of galls; that the galls are the most perishable ingredient, the quantity of these, which gives the greatest blackness at first (that is, about equal parts with the vitriol), being insufficient to maintain the colour; that, for a durable ink, the quantity of galls cannot be much less than three times that of the vitriol; that it cannot be much greater without lessening the blackness of the ink; that by diminishing the quantity of water, the ink is rendered blacker and more durable; that distilled water, rain-water, and hard spring-water, have the same effects; that white wine produces a deeper black colour than water; that the colour produced by vinegar is deeper than that by wine; that proof-spirit extracts only a reddish brown tinge; that the last-mentioned tincture sinks into, and spreads upon, the paper; and hence the impropriety of adding spirit of wine to ink, as is frequently directed, to prevent mouldiness or freezing; that other astringents, as oak-bark, bistort, sloe-bark, &c. are not so effectual as galls, nor give so good a black, the colour produced by most of these, excepting oak-bark, being greenish; that the juice of sloes does not produce a black colour with martial vitriol; but that, nevertheless, the writing made with it becomes black, and is found to be more durable than common ink: that inks made with saturated solutions of iron, in nitrous, marine, or acetous acids, in tartar, or in lemon juice, were much inferior to the ink made with martial vitriol; that the colour of ink is depraved by adding quicklime, which is done with an intention of destroying any superabundant acid which may be supposed to be the cause of the loss of the colour of ink; that the best method of preventing the effects of this superabundant acid is probably by adding pieces of iron to engage it; that this conjecture is confirmed by an instance the author had heard, of the great durability of the colour of an ink in which pieces of iron had been long immersed; and lastly, that a decoction of logwood used instead of water, sensibly improves both the beauty and deepness of the black, without disposing it to fade. The same author observes, that the addition of gum-arabic is not only useful, by keeping the colouring matter suspended in the fluid, but also by preventing the ink from spreading, by which means a greater quantity of it is collected on each stroke of the pen. Sugar, which is sometimes added to ink, is found to be much less effectual than gums, and to have the inconvenience of preventing the drying of the ink. The colour of ink is found to be greatly injured by keeping the ink in vessels made of copper or of lead, and probably of any other metal, which the vitriolic acid can dissolve.

The foregoing experiments point out the best proportions of the ingredients for ink, one part of green vitriol, one part of powdered logwood, and three parts of powdered galls. The best menstruum appears to be vinegar or white wine, though for common use water is sufficient. If the ink be required to be of a full colour, a quart, or at most three pints, of liquor, may be allowed to three ounces of galls, and to one ounce of each of the other two ingredients. Half an ounce of gum may be added to each pint of the liquor. The ingredients may be all put together at once in a convenient vessel, and well shaken four or five times each day. In ten or twelve days the ink will be fit for use, though it will improve by remaining longer on the in-

Ink.

gredients. Or it may be made more expeditiously, by adding the gum and vitriol to a decoction of galls and logwood in the menstruum. To the ink, after it has been separated from the feculencies, some coarse powder of galls, from which the fine dust has been sifted, together with one or two pieces of iron, may be added, by which its durability will be secured.

Such is the substance of the discoveries and inquiries made by Dr Lewis and other chemists, relative to the composition of black writing ink, and upon modifications of them, most of the methods hitherto followed in making it have been founded. It might be supposed that after the determination, by such authority, of the relative proportions of the usual ingredients, it would only have been necessary to attend to that proportion, and that the result would be uniformly satisfactory. Experience, however, has shewn the reverse of this; and it is often found that the same ingredients, and the same proportions of them, produce inks of very different qualities. This arises from two causes, which were not apparent to the experimenting chemist. His attention was chiefly directed to the *immediate* effect produced by the mixture he prepared, or the additions made to it. Hence his experiments generally led him to the formation of a good black *dye*, if applied to immediate use; whilst the *ultimate* effect of the action of the atmosphere on the liquid itself, and the decomposition which frequently resulted, from the quantity of vegetable matter contained in it, were seldom brought under his notice. To these two causes, as well as the various modes of extract and of mixture, are to be attributed the very different results which have arisen from the use of the same ingredients and the same proportions of them; and on the connexion and regulation of these two agents, we believe the quality of the ink to depend, as much as upon the nature and proportion of the materials employed. This opinion is strengthened by the information we have received from Mr Morison (the extent of whose ink manufactories is a remarkable instance of the importance of the most minute branch of the arts, at the present day, in Great Britain), who has assured us, that he never could depend on the quality of the ink which was to be produced from any mixture of ingredients, however well manipulated, or however strong, until he adopted a method of abstracting that part of the vegetable ingredients which induced decomposition; a process which required much time and attention, but in the accomplishment of which so full opportunity was given for the action of the atmosphere that the liquid was not liable to be afterwards affected by either cause.

In some attempts made by Dr Lewis to endow writing ink with the great durability of that of the ancients, as well as the properties which it has at present, he first thought of using animal glues, and then of oily matters. "I mixed both lamp-black," says he, "and ivory-black with solutions of gum-arabic, made of such consistence as just to flow sufficiently from the pen. The liquors wrote of a fine black colour; but when dry, part of the colour could be rubbed off, especially in moist weather, and a pencil dipped in water washed it away entirely.

"I tried solutions of the animal-glues with the same event. Isinglass or fish-glue being the most difficultly dissoluble of these kinds of bodies, I made a decoction of it in water, of such strength that the liquor concreted into a jelly before it was quite cold. With this jelly, kept fluid by sufficient heat, I mixed some ivory-black. Characters drawn with this mixture on paper bore rubbing much better than the others, but were discharged without much difficulty by a wet pencil.

"It was now suspected, that the colour could not be sufficiently fixed on paper without an oily cement. As oils themselves are made miscible with watery fluids by the intervention of gum, I fixed some of the softer painters' varnish, after mentioned, with about half its weight of a thick mucilage of gum arabic, working them well together in a mortar till they united into a smooth uniform mass. This was beaten with lamp-black, and some water added by little and little, the rubbing being continued till the mixture was diluted to a due consistence for writing. It wrote freely, and of a full brownish black colour; the characters could not be discharged by rubbing, but water washed them out, though not near so readily as any of the foregoing. Instead of the painters' varnish or boiled oil, I mixed raw linseed oil in the same manner with mucilage and lamp-black; and on diluting the mixture with water, obtained an ink not greatly different from the other.

"Though these oily mixtures answered better than those with simple gums or glues, it was apprehended that their being dischargeable by water would render them unfit for the purposes intended. The only way of obviating this imperfection appeared to be, by using a paper which should admit the black liquid to sink a little into its substance. Accordingly, I took some of the more sinking kinds of paper, and common paper made damp as for printing, and had the satisfaction to find, that neither the oily nor the simple gummy mixtures spread upon them so much as might have been expected, and that the characters were as fixed as could be desired, for they could not be washed out without rubbing off part of the substance of the paper itself.

"But a further improvement may yet be made, namely, that of uniting the ancient and modern inks together; or using the common vitriolic ink instead of water, for tempering the ancient mixture of gum and lamp-black. By this method it should seem that the writings would have all the durability of those of former times, with all the advantage that results from the vitriolic ink fixing itself in the paper. Even where the common vitriolic mixture is depended on for the ink, it may in many cases be improved by a small addition of the ancient composition, or of the common Indian ink, which answers the same purpose. When the vitriolic ink is dilute, and flows so pale from the pen, that the fine strokes, on first writing, are scarcely visible, the addition of a little Indian ink is the readiest means of giving it the due blackness. By this admixture it may be presumed also that the vitriolic ink will be made more durable, the Indian ink in some measure covering it, and defending it from the action of the air. In all cases, where Indian ink or other similar compositions are employed, cotton should be used in the ink-stand, to prevent the settling of the black powder."

There is little doubt that the monkish ink was a composition of this nature, combining in some degree the ancient and modern materials. The ancient ink must have been very similar to the Indian or Chinese cakes. Pliny and Vitruvius both mention it as a preparation of soot, or lamp-black, with glue or gum; and Dioscorides gives the proportions of three parts of soot to one of gum. To this the liquor extracted from the cuttle-fish had sometimes been added. When this could not be had, there is indeed great reason to believe that some of the modern vitriolic ingredients were added by the ancients; many of the manuscripts of the Greek and Roman authors, erased by the monks, having been found to retain as much of the vitriolic principle as to become again legible on the application of chemical tests.

In the Philosophical Transactions for 1787, Dr Blagden gives some account of a method of restoring decayed inks so as to render them legible. His experiments originated from a conversation with Mr Astle, on the question whether the inks made eight or ten centuries ago, and which are found to have preserved their colour very well, were made of the same materials now employed or not? In order to decide the question, Mr Astle furnished the doctor with several manuscripts on parchment and vellum from the ninth to the fifteenth centuries inclusively. Some of these were still very black; others of different shades, from a deep yellowish brown to a very pale yellow, in some parts so faint that it could scarcely be seen. This was tried with simple and phlogisticated alkalies, the mineral acids, and infusion of galls. From these experiments it appeared that the ink anciently employed was of the same nature as at present. The letters turned of a reddish or yellowish brown, with alkalies became pale, and were at length obliterated by the diluted mineral acids. The drop of acid liquor, which had been put upon a letter, changed to a deep blue or green on the addition of phlogisticated alkalies; with an infusion of galls, in some cases the letters acquired a deep tinge, in others a slight one. "Hence," says the doctor, "it is evident that one of the ingredients was iron, which there is no reason to doubt was joined with the vitriolic acid; and the colour of the more perfect manuscripts, which in some was a deep black, and in others a purplish black, together with the restitution of that colour in those which had lost it by the infusion of galls, sufficiently proved that another of the ingredients was astringent matter, which from history appears to have been that of galls. No trace of a black pigment of any sort was discovered; the drop of acid, which had completely extracted a letter, appearing of an uniform pale and ferruginous colour, without an atom of black powder, or other extraneous matter, floating in it."

In considering the methods of restoring the legibility of decayed writings, our author observes, that perhaps one of the best may be to join phlogisticated alkali with the calx of iron which remains; because the precipitate formed by these two substances greatly exceeds that of the iron alone. On this subject Dr Blagden disagrees with Mr Bergmann; but to bring the matter to a test, the following experiments were made.

1. The phlogisticated alkali was rubbed in different quantities upon the bare writing. This, in general, produced little effect, though, in a few instances, it gave a bluish tinge to the letters, and increased their intensity; "probably," says the doctor, "where something of an acid nature had contributed to the diminution of their colour." 2. By adding, besides the alkali, a diluted mineral acid to the writing, our author found his expectations fully answered; the letters then changing quickly to a very deep and beautiful blue. It is but of little consequence whether the acid or phlogisticated alkali be first added; though upon further consideration the doctor inclined to begin with the alkali. The reason is, that when the alkali is first put on, the colour seems to spread less, and thus not to hurt the legibility of the writing so much as would otherwise be done. His method is to spread the alkali thin over the writing with a feather, then to touch it as gently as possible upon or nearly over the letters with the diluted acid by means of a feather or bit of stick cut to a blunt point. The moment that the acid liquor is applied, the letters turn to a fine blue, beyond comparison stronger than the original trace of the letter; and by applying a bit of blotting-paper to absorb the superfluous liquid, we may in a great measure avoid the staining of the parchment; for it is this superfluous liquor which, absorbing part of the colouring matter from the letters, becomes a dye to whatever it touches. Care ought, however, to be taken not to allow the blotting-paper to come in contact with the letters, because the colouring matter may easily be rubbed off while soft and wet. Any one of the three mineral acids will answer the purpose effectually. Dr Blagden commonly uses the marine. But whichever of the three is used, it ought to be diluted so far as not to be in danger of corroding the parchment; after which the degree of strength seems not to be a matter of great nicety.

Another method of restoring the legibility of old writings is by wetting them with an infusion of galls in white wine; but this is subject to the same inconvenience with the former, and is besides less efficacious. The doctor is of opinion that the acid of the galls by itself would be better for the purpose than the infusion of the whole substance of them; and he thinks also that a preferable kind of phlogisticated alkali might be prepared either by purifying the common kind from iron as much as possible, or by making use of the volatile alkali instead of the fixed. Mr Astle mentions a method of restoring the legibility of decayed writings; but says that it ought not to be hazarded, lest a suspicion of deceit should arise.

The illegibility of modern manuscripts, compared with those of an earlier date, is a matter of much interest, and has of late excited considerable inquiry. It appears to us, that the greater durability of the colour of the ink in old manuscripts is owing not only to the strength of the ink, but to the quality of the paper and vellum. The strength of the astringent or *tannin* principle is acknowledged on all hands to be that on which the durability of a vitriolic ink chiefly depends. Now that principle is strong not only in old vellum, but it is retained to a considerable extent in old paper made from linen rags. The vellum formerly used was prepared by a tedious process, by which tannin was largely imparted to it in the same manner as to leather; and to this cause old vellum owes its deep brown colour more than to mere age. In like manner, the paper, instead of being bleached, as is now done, with oxymuriatic acid, to *bring up* the colour, as it is called, but, in fact, to destroy the natural colour of the paper, and to deprive it of one of its most valuable qualities, was allowed to retain somewhat of its original *flax* colour, and with its colour a large proportion of the astringent quality on which the tenuity of the paper, as well as its preservative property, depended. On that strong vellum, parchment, and paper, our ancestors wrote with an ink, the component parts of which seem to have been the same as of that now in use; but as they wrote more seldom, and were not in so great haste, as their descendants, they were content to use their ink so *thick*, that the quantity of gum in it was sufficient to hold a very strong mixture of the other ingredients in suspension. This superabundance of gum or glue was not only serviceable in this respect, but it also acted as a varnish, defending the ink from the corrosive action of the atmosphere. Nor were these the only precautions taken. It will be observed, that those writings on vellum which are in the best preservation, are not only of a deep brown shade, and the ink with an apparent *body* of colour, but the *grain* side of the vellum, or that not written upon, is smooth, almost as if it had been burnished. This seems to have been done with animal glue, and afterwards well rubbed. The ink was thus not only preserved from the action of the air on the one side by the varnish incorporated with it, but protected on the other by the polished surface of the parchment.

Taking these circumstances into consideration, and giving them their due weight, we feel convinced that any effectual plan for giving durability to the public records of the kingdom or other deeds of importance, must commence with the improvement of the paper and vellum upon which they are written. This is a matter deserving the attention of government, and the correction of which is within its reach. The books of records kept in the public offices are or ought to be under its superintendence; and the only deeds the preservation of which is of importance are written upon stamped paper, the issue of which is also within the control of the government. By offering premiums for the manufacture of paper in which the tannin or astringent principle is most effectually preserved or introduced, and using proper precautions respecting the ink with which the deeds are written, we can see nothing in the nature or composition of either to prevent us securing at the very least as great a degree of durability as pertains to the early records of the kingdom.

Indian Ink, a valuable black for water-colours, brought from China and other parts of the East Indies, sometimes in large rolls, but more commonly in small quadrangular cakes, and generally marked with Chinese characters. Dr Lewis, from experiments made on this substance, has shewn that it is composed of fine lamp-black and animal glue; and, accordingly, for the preparation of it, he desires us to mix the lamp-black with as much melted glue as is sufficient to give it a tenacity proper for being made into cakes; and these when dry, he tells us, answered as well as those imported from the East Indies, both with regard to the colour and the freedom of working. Ivory-black, and other charcoal blacks, levigated to a great degree of fineness, answered as well as the lamp-black; but in the state in which ivory-black is commonly sold, it proved much too gritty, and separated too hastily from the water.

Red Ink. The red ink in common use for writing or ruling is a decoction of Brazil wood in vinegar, the colour of which is raised by alum. It answers every ordinary purpose of business, but the colour is evanescent, especially on highly bleached paper, the oxymuriatic acid in which turns the ink first of a purple colour and then gradually whitens it. No red ink which will stand exposure to the air has yet been discovered, save a thin pigment of vermilion, with which many old bibles were ruled; but it can easily be washed off.

Blue Ink. The dye commonly called *liquid blue* is frequently used for writing, being, if well made, durable; and when diluted with water forms the ink with which the *faint lines* in ruling are drawn. It is made of indigo dissolved in sulphuric acid, the strength of the acid being afterwards reduced by throwing into the liquid mass pieces of chalk or of an alkali.

For other coloured inks see *Colour Making*.

Printing Ink, is totally different from Indian ink, or that made use of in writing. It is an oily composition, of the consistence of an ointment. The method of preparing it was long kept a secret by those whose employment it was to make it, and who were interested in concealing it; and even yet it is but imperfectly known. The properties of good printing ink are, to work clean and easily, without daubing the types or tearing the paper; to have a fine black colour; to wash easily off the types; to dry soon; and to preserve its colour, without turning brown. This last, which is a most necessary property, is effectually obtained by setting fire to the oil with which the printing ink is made for a few moments, and then extinguishing it by covering the vessel.[1] It is made to wash easily off the types, by using soap as an ingredient; and its working clean depends on its having a proper degree of strength, which is given by a certain addition of rosin. A good deal, however, depends on the proportion of the ingredients to each other; for if too much soap is added, the ink will work very foul, and daub the types to a greater degree. The same thing will happen from using too much black, at the same time that both the soap and black hinder the ink from drying; whilst too much oil and rosin tear the paper, and hinder it from washing off. The following receipt has been found to make printing ink of a tolerable good quality: Take a Scotch pint of linseed oil, and set it over a pretty brisk fire in an iron or copper vessel capable of holding three or four times as much. When it boils strongly, and emits a thick smoke, kindle it with a piece of paper, and immediately take the vessel off the fire. Let the oil burn for about a minute; then extinguish it by covering the vessel; after it has grown pretty cool, add two pounds of black rosin, and one pound of hard soap cut into thin slices. If the oil is very hot when the soap is added, almost the whole mixture will run over the vessel. The mixture is then to be set again over the fire; and when the ingredients are thoroughly melted, a pound of lamp-black, previously put through a lawn sieve, is to be stirred into it. The whole ought then to be ground on a marble stone, or in a levigating mill.

Though the above receipt is greatly superior to any that has been hitherto published, all of which are capitally deficient in not mentioning the necessary ingredients of rosin and soap; yet it must be acknowledged that ink made in this manner is inferior in point of colour, and is likewise more apt to daub the types and make an indistinct impression, than such as is prepared by some of those who make the manufacture of this commodity their employment; so that either a variation in the proportion of the ingredients, a nicety in the mixture, or some additional ingredient, seems necessary to bring it to the requisite perfection.

Ink for the rolling Press, is made of linseed oil burned in the same manner as that for common printing ink, and then mixed with Francfort-black, and finely ground. There are no certain proportions which can be determined in this kind of ink; every workman adding oil or black to his ink as he thinks proper, in order to make it suit his own taste. Some, however, mix a portion of common boiled oil, which has never been burned; but this must necessarily be a bad practice, as such oil is apt to go through the paper; a fault very common in prints, especially if the paper is not very thick. No soap is added; because the ink is not cleared off from the copperplates with alkaline ley as in common printing, but with a brush dipped in oil.

Lithographic Ink. The ink used for writing or drawing in lithography is described under that article. For printing ink to be used in lithography, prepare a varnish or varnishes, of various degrees of tenuity, by boiling and burning old linseed oil in an iron pot with a closely fitting metal cover. When the varnish is of the thickness required, throw in some pieces of stale bread to absorb the fatty matter. Into this varnish, when cold, grind lamp-black or Francfort-black, adding a little indigo and rose-pink, which give depth to the black. It must be ground until so fine that no particles are observed on turning it over with a palette knife. For blue, use indigo; for red, vermilion.

Sympathetic Ink, a liquor with which a person may write, and yet nothing appear on the paper after it is dry, till some means are used, as holding the paper to the fire, or rubbing it over with some other liquor, to make it visible.

These kinds of ink may be divided into seven classes, with respect to the means used to make them visible, viz. 1. such as become visible by passing another liquor over them, or by exposing them to the vapour of that liquor; 2. those that do not appear so long as they are kept close, but soon become visible on being exposed to the air; 3. such as appear by strewing or sifting some very fine powder of any colour over them; 4. those which become visible by being exposed to the fire; 5. such as become visible by heat, but disappear again by cold or the moisture of the air; 6. those which become visible by being wetted with water; and, 7. such as appear of various colours.

The first class contains four kinds of ink, viz. solutions of lead, bismuth, gold, and green vitriol, or sulphate of iron. The two first become visible by the contact of sulphureous liquids or fumes. For the first, a solution of common sugar of lead in water answers very well. With this solution write with a clean pen, and the writing when dry will be totally invisible; but if it be wetted with a solution of

[1] This is mentioned by Dr Lewis in his *Philosophical Commerce of Arts*; but he seems not to have been acquainted with the method of giving it the other necessary properties.

hepar sulphuris, or of orpiment, dissolved by means of quicklime, or exposed to the strong vapours of these solutions, the writing will appear of a brown colour, more or less deep, according to the strength of the sulphureous fume. By the same means the solution of nitrate of bismuth will appear of a deep black.

The sympathetic ink prepared from gold depends on the property by which that metal precipitates from its solvent on the addition of a solution of tin. Write with a solution of gold in nitro-muriatic acid, and let the paper dry gently in the shade; nothing will appear for the first seven or eight hours. Dip a pencil in the solution of tin, and draw it lightly over the invisible characters, they will immediately appear, of a purple colour.

Characters written with a solution of green vitriol will likewise be invisible when the paper is dry; but if wetted with an infusion of galls, they will immediately appear as if written with common ink. If, instead of this infusion, a solution of an alkaline prussiate be used, the writing will appear of a deep blue.

To the second class belong the solutions of all those metals which are apt to attract oxygen from the air, such as lead, bismuth, silver, &c. The sympathetic ink of gold already mentioned belongs also to this class; for if the characters written with it are long exposed to the air, they become by degrees of a deep violet colour, nearly approaching to black. In like manner, characters written with a solution of nitrate of silver are invisible when newly dried, but being exposed to the sun, appear of a gray colour like slate. To this class also belong solutions of sugar of lead, nitrates of copper and of mercury, acetate of iron, and muriate of tin. Each of these has a particular colour when exposed to the air; but they corrode the paper.

The third class of sympathetic inks contains such liquids as have some kind of glutinous viscosity, and at the same time are long in drying; by which means, though the eye cannot discern the characters written with them upon paper, the powders strewed upon them immediately adhere, and thus make the writing become visible. Of this kind are urine, milk, the juices of some vegetables, weak solutions of the deliquescent salts, and other liquids.

The fourth class, comprehending all those that become visible by being exposed to the fire, is very extensive, as it contains all those colourless liquids in which the matter dissolved is capable of being reduced, and of reducing the paper into a sort of charcoal by a small heat. Sulphuric acid, diluted with as much water as will prevent it from corroding the paper, makes a good ink of this kind. Letters written with this fluid are invisible when dry, but instantly on being held near the fire appear as black as if written with the finest ink. Juice of lemons or onions, a solution of sal ammoniac, green vitriol, &c. answer the same purpose.

The fifth class comprehends only a solution of muriate of cobalt.

The sixth class comprehends such inks as become visible when characters written with them are wetted with water. They are made of all such substances as deposit a copious sediment when mixed with water, dissolving only imperfectly in that fluid. Of this kind are dried alum, sugar of lead, vitriol, and other substances. We have therefore only to write with a strong solution of these salts upon paper, and the characters will be invisible when dry; but when we apply water, the small portion of dried salt cannot again be dissolved in the water. Hence the insoluble part becomes visible on the paper, and shews the characters written in white, gray, brown, or any other colour which the precipitate assumes.

Lastly, characters may be made to appear of a fine crimson, purple, or yellow, by writing on paper with solution of muriate of tin, and then passing over it a pencil dipt in a decoction of cochineal, Brazil-wood, log-wood, yellow-wood, or the like.

A treatise upon inks was published by Peter Caniparius, professor of Medicine at Venice, of which an edition was printed at London in 1660. It is divided into six parts. The first treats of inks made from pyrites, stones, and metals; the second of such as are made from metals and calces; the third of those which are prepared from soots and vitriols; the fourth of the different kinds of inks used by the *librarii* or book-writers, by printers, and engravers: likewise of staining or writing upon marble, stucco, or scagliolia, and of encaustic modes of writing; of liquids for painting or colouring leather and linen or woollen cloth, and of restoring inks that had been decayed by time; together with many methods of effacing writing, restoring decayed paper, and different modes of secret writing. The fifth treats of writing inks made in different countries from gums, woods, the juices of plants, and the like, as well as of different kinds of varnishes. The sixth treats of the different methods of extracting vitriol, and the chemical uses of it.

Weckerus, in a treatise *de Secretis*, printed at Basil in 1612, contains a number of curious particulars concerning ink. He also gives receipts for making gold and silver inks, composed both with these metals and without them; and directions for making inks for secret writing, and for effacing them, though in this last part there are many particulars bordering too much on the marvellous.

INK *Stones*, a kind of small round stones, of a white, red, gray, yellow, or black colour, containing a quantity of native martial vitriol, from which they derive the property of making ink, and hence their name. They are almost entirely soluble in water, and besides their other ingredients, contain also a portion of copper and zinc.

INLAND, a name for any part of a country at a distance from the coast.

INLAND *Navigation*. See NAVIGATION, INLAND.

INLEASED, in our old writers, signifies entangled or ensnared. It is a term used in the champion's oath.

INMATES, such persons as are admitted for their money to live in the same house or cottage with another person, in different rooms, but entering by the same door; being usually supposed to be poor, and not able to maintain entire house themselves.

INN, or INNVERTE, a circle of the Austrian province of the Upper Ens, extending over 1308 square miles, containing 5 cities, 26 market towns, and 3688 villages and farms, with 37,236 houses, and 181,633 inhabitants.

INN, a place appointed for the relief and entertainment of travellers.

INNS. Our colleges of municipal or common law professors and students, are called *inns;* this being the old English word for houses of noblemen, bishops, and others of extraordinary note, and of the same signification with the French word *hotels.*

INNS *of Court* are so called, according to some, because the students there are to serve and attend the courts of judicature; or because these colleges anciently received none but the sons of noblemen, and the better sort of gentlemen, who, as Fortescue affirms, were to be there qualified to serve the king in his court. In the time of Fortescue, there were about two thousand students in the inns of court and chancery, all of whom were *filii nobilium*, or gentlemen born. But this custom gradually fell into disuse; so that in the reign of Queen Elizabeth, Sir Edward Coke does not reckon above one thousand students, and the number at present is very considerably less. For this Judge Blackstone assigns the following reasons: 1. Because the inns of chancery, being now almost totally filled by the inferior branches of the profession, are neither commodious nor proper for the resort of gentlemen of any rank or figure; so that there are very rarely any young students entered at the inns of chancery. 2. Because in the inns of court all sorts of regimen and academical superintendence, either with regard to morals or studies, have been found impracticable, and therefore entirely neglected. 3. Because persons of birth and fortune, after having finished their usual courses at the universities, have seldom leisure or resolution sufficient to enter upon a new scheme of study at a new place of instruction; wherefore few gentlemen now resort to the inns of court, except those for whom the knowledge of practice is absolutely necessary in such as are intended for the profession.

Our inns of court, justly famed for the production of men of learning in the law, are governed by masters, principals, benchers, stewards, and other officers; and they have public halls for exercises, readings, and the like, which the students are obliged to attend for a certain number of years, before they can be admitted to plead at the bar. These societies have not, however, any judicial authority over their members; but instead of this there exist among themselves certain orders or regulations, which have by consent the force of laws. For lighter offences persons are only excommoned, or put out of commons; for greater, they lose their chambers, and are expelled the college; and when once expelled out of one society, they are never received by any of the others. The gentlemen in these societies may be divided into benchers, outer-barristers, inner-barristers, and students.

The four principal inns of court are, the Inner Temple and Middle Temple, formerly the dwelling of the Knights Templars; and Lincoln's Inn and Gray's Inn, which anciently belonged to the Earls of Lincoln and Gray. The other inns are the two Serjeants' Inns.

INNS *of Chancery* were probably so called, because anciently inhabited by such clerks as chiefly studied the forming of writs, which regularly belonged to the cursitors, who are of chancery.

The first of these is Thavies Inn, begun in the reign of Edward III., and afterwards purchased by the society of Lincoln's Inn. Besides this, there are New Inn, Symond's Inn, Clement's Inn, Clifford's Inn, Staple Inn, belonging to the merchants of the staple; Lion's Inn, anciently a common inn with the sign of the lion; Furnival's Inn, and Bernard's Inn.

Heretofore these were preparatory colleges for younger students; and many were entered there, before they were admitted into the inns of court. Now they are mostly occupied by attorneys, solicitors, and others. They all belong to one or other of the inns of court, who formerly used to send yearly some of their barristers to read to them.

INNATE IDEAS, those ideas supposed to be stamped on the mind from the first moment of its existence, and which it brings into the world with it; a doctrine which Mr Locke has taken great pains to refute. See METAPHYSICS.

INNISFAIL (formed from *Innis Bheal*, the island of Bheal), one of the ancient names of Ireland, which is so denominated from *Bheal* or *Baal*, the principal object of adoration amongst the ancient inhabitants of the British isles. Innisfail has been translated the *Island of Destiny*, because *Bheal* was sometimes taken for *Fate* or *Providence*.

INNISFALLEN, an island in the lake of Killarney, in the county of Kerry, and province of Munster, containing the ruins of a very ancient religious house, founded by St Finian, the patron saint of these parts, to whom the cathedral of Aghadoe is also dedicated. The remains of this abbey are very extensive, and its situation is retired and romantic.

INNISHANNON, a town in the county of Cork, and province of Munster, 134 miles from Dublin, and situated on the river Bandon, six miles from Kinsale. The river is navigable to Collier's Quay, about half a mile below the place. This place was formerly walled, and of some note. The town of Innishannon, together with its ferry, were granted to Philip de Barry by letters patent from Henry V. in 1412.

INNISHIRKAN, an island situated between Cape Clear Island and Baltimore Bay, in the county of Cork, and province of Munster. In this island stood the castle of Dunelong, possessed by the O'Driscolls, which was surrendered to Captain Harvey on the 23d of February 1602, after the defeat of the Spaniards. There was afterwards a regular fortification erected on part of the island, which was garrisoned in Queen Anne's time, but it has long been dismantled. About a mile to the south are the remains of an ancient abbey, founded 1460, for Franciscans, by Florence O'Driscoll.

INNISKILLING, INNISKILLEN, a borough town of Ireland, in the county of Fermanagh, and province of Ulster, situated between three lakes. It is about twenty-four miles east of Ballyshannon, and seventy-nine north-west of Dublin, this place giving title of viscount to the family of Cole. Its inhabitants distinguished themselves in several considerable engagements in the wars of Ireland at the Revolution, and of their number, a regiment of dragoons, bearing the title of the Inniskillen Dragoons, was mostly formed. This regiment is the sixth of dragoons in the British army.

INNOCENTS' DAY, a festival of the Christian church, observed on the 28th of December, in memory of the massacre of the innocent children by the command of Herod king of Judæa.

INNUENDO (from *innuo*, I nod or beckon), is a word frequently used in writs, declarations, and pleadings, to ascertain a person or thing which was named before, but left doubtful, as, he (*innuendo*, the plaintiff) did so and so; mention being before made of another person. In common conversation or writing, an innuendo denotes an oblique hint or distant reference, in contradistinction to a direct and positive charge.

INNYCOTTA, a town of Hindostan, province of Berar, in the province of Gundwana, situated upon the eastern bank of the Warda river, 57 miles S. W. from Nagpoor. Lat. 20° 35′ N; Long. 79° 10′ E.

INO, in fabulous history, a daughter of Cadmus and Harmonia, who nursed Bacchus. She married Athamas, king of Thebes, after he had divorced Nephele, by whom he had two children, Phryxus and Helle. Ino became mother of Melicerta and Learchus; and soon conceived an implacable hatred against the children of Nephele, because they were to ascend the throne in preference to her own. Phryxus and Helle were informed of Ino's machinations, and escaped to Colchis on a golden ram. Juno, jealous of Ino's prosperity, resolved to disturb her peace; and more particularly because she was a descendant of her greatest enemy Venus. Tisiphone being sent by order of Juno to the house of Athamas, she filled the whole palace with such fury, that Athamas, taking Ino to be a lioness and her children whelps, pursued her and dashed her son Learchus against a wall. Ino escaped the fury of her husband, and from a high rock threw herself into the sea, with Melicerta in her arms. The gods pitied her fate; and Neptune transformed her into a sea deity, afterwards denominated Leucothoe. Melicerta also became a sea god, and was known by the name of Palemon.

INOA, festivals in memory of Ino, celebrated yearly with sports and sacrifices at Corinth. An anniversary sacrifice was also offered to Ino at Megara, where she was first worshipped under the name of Leucothoe. Another festival of the same description was also celebrated in Laconia, in honour of the same goddess.

INOCULATION, or BUDDING, in *Gardening*. See HORTICULTURE.

INOCULATION, in a physical sense, is used to indicate the transplantation of distempers from one subject to another, particularly for the engraftment of the small-pox; a practice which, though of ancient use in eastern countries, is but of modern date amongst us, at least under the direction of art. See SURGERY and VACCINATION.

The time and place in which the method of inoculating for the small-pox was first used, are equally unknown. Accident probably gave rise to it. Pylarini says, that amongst the Turks it was not attended to, excepting amongst the meaner sort. Dr Russell informs us[1] that no mention is made of it by any of the ancient Arabian medical writers who are known in Europe; and the native physicians of Arabia assert, that nothing is to be found regarding it in any of those of a more modern date. He further says, that he engaged some of his learned Turkish friends to make inquiry concerning this matter; but they did not discover any thing on the subject of inoculation in the writings of their physicians, historians, or poets. Until the beginning of the eighteenth century, all the accounts we have of inoculating the small-pox are merely traditional. The silence on this subject observed amongst writers in the countries where the practice obtained, Dr Russell supposes, with great probability, to be owing to the circumstance that the physicians there never countenanced or engaged in it. It is also remarkable, that before Pylarini's letter to the Royal Society in 1701, and for several years afterwards, this practice is not noticed by any of the most inquisitive travellers. On this Dr Russell very justly observes, that customs the most common in distant countries are often the least apt to attract the observation of travellers, who, engaged in other pursuits, are indebted to accident for the knowledge of such things as the natives seldom talk of, from a belief that they are known to all the world.

The first accounts we have concerning inoculation, are from two Italian physicians, Pylarini and Timoni, whose letters on the subject may be consulted in the *Philosophical Transactions* abridged (vol. v. p. 370). The first is dated in 1701, the second in 1713. But whether our inquiries extend to countries abroad, or are confined to our own, inoculation, in one mode or other, has been practised from time immemorial; in Great Britain and its adjacent isles we have well authenticated accounts, extending farther backwards than any we have received from the continent. Dr Williams of Haverfordwest, who wrote upon inoculation in 1725, proves that it had been practised in Wales, though in a somewhat different form, time out of mind. Mr Wright, a surgeon in that principality, says, that *buying the small-pox* is both a common practice, and of long standing, in that neighbourhood. He mentions, that in Pembrokeshire there are two large villages near the harbour of Milford, more famous for this custom than any other, namely, St Ishmael's and Marloes. The old inhabitants of these villages say, that it has been a common practice; and that one William Allen of St Ishmael's, who was ninety years of age in 1722, declared to some persons of good sense and integrity, that this practice was used all his time, and that he well remembered his mother telling him that it was a common practice all her time, and that she got the small-pox by inoculation.

Dr Alexander Monro senior informs us, that in the Highlands of Scotland and some of the adjacent isles, the custom through ages had been, to put their children to bed with those who laboured under a favourable small-pox, and to tie worsted threads about their children's wrists, after having drawn them through variolous pustules.

According to the result of Dr Russell's inquiries, the Arabians asserted that the inoculation of the small-pox was the common custom of their ancestors, and that they had no doubt of its being as ancient as the disease itself. It is remarkable, that *buying the small-pox* is the name universally applied in all countries to the method of procuring the disease. It is true that there are other terms; but in Wales and in Arabia, as well as in many other countries, this is the usual appellation. From the identity of the name, and the little diversity observable in the manner of performing the operation, it is probable that the practice of inoculation in these countries was originally derived from the same source. It is also in all probability of great antiquity.

In the year 1717, Lady Mary Wortley Montague, wife of the English ambassador at Constantinople, had her son inoculated there at the age of six years; he had but few pustules, and soon recovered. In April 1721, inoculation was successfully tried upon seven condemned criminals in London, by permission of his Majesty. In 1722, Lady Mary Wortley Montague had a daughter six years old inoculated in this island; soon after which, the children of the royal family who had not had the small-pox were inoculated with success; then followed some of the nobility, and the practice soon became general. And here we date the commencement of inoculation under the direction of art.

INQUISITION, in the Church of Rome, a criminal tribunal, charged with the detection, prosecution, and punishment of heresy, apostasy, and other crimes against religion.

This formidable jurisdiction, created for the express purpose of repressing free inquiry in matters of religion, and maintaining the unity of the faith, was first instituted about the beginning of the thirteenth century, when Innocent III. appointed a commission to prosecute and punish the heretics of Narbonne. In 1203, the Pope employed Pierre de Castelnau and Raoul, monks of Cîteaux, attached to the monastery of Frontfroine in Narbonne, to preach against the heresy of the Albigenses. The labours of these missionaries were not altogether fruitless, as is proved by an authentic act which William Castel has inserted in his History of the Counts of Toulouse, and which was agreed to in the year 1204. They appear to have made a considerable impression, and, in particular, to have induced the inhabitants of Toulouse to bind themselves by an oath to maintain the Catholic religion, and to combat heresy by every means in their power. The success which Castelnau and Raoul had thus obtained in their mission, encouraged the Pope to put in execution a project which he had formed for introducing into the Catholic Church inquisitors independent of the bishops, who should, as delegates of the Holy See, have the right of prosecuting heretics.

With this view he named as apostolic legates, the Abbot of Cîteaux, and the two monks Castelnau and Raoul, who received orders to take the necessary measures for bringing back heretics to the Catholic faith, and also for delivering to the secular power, after excommunication, those who refused submission; a penalty which involved the seizure of their goods, and the proscription of their persons. And, in order to facilitate the execution of his design, he solicited Philip II., king of France, his oldest son Louis, and the counts, viscounts, and barons of the kingdom, to prosecute heretics of whatsoever rank they might be, and to seize the goods of all persons who might be convicted of favouring heresy, or who had not laboured to destroy it; promising them, as a recompense for their zeal, plenary indulgences, similar to those granted to the Christians who had assumed the cross, and repaired to the Holy Land to combat against the Infidels. But the papal legates experienced great difficulties in the execution of their mission, which was distasteful to the bishops; the king of France took no part in the affair; and the Counts of Toulouse, Foix, Beziers, Carcassonne, and other seigneurs or great lords of the provinces, seeing that the Albigenses had singularly multiplied, and

[1] *Philosophical Transactions*, vol. lviii. p. 142.

persuaded that only a very small number of them would freely consent to abjure their opinions, refused to expel a body of men, the loss of whom would weaken the population of their estates, and consequently prove injurious to their interests. Nor was the force of this motive lessened by the consideration that these heretics were generally peaceable and obedient subjects. The legates were consequently discouraged, and one of their number applied to the Pope for permission to retire to his monastery. But the Holy Father, firm to his purpose, exhorted him to prosecute the enterprise with new ardour, and at the same time addressed new briefs to Philip II., reproaching him for his indifference, and to the Archbishop of Narbonne and to the Bishop of Beziers, censuring the mode in which they had acted towards his legates.

In these circumstances, Castelnau and Raoul commenced preaching to the heretics, and even held conferences with some of their leaders; but, as might have been expected, the number of persons converted by them was exceedingly small. Arnauld, Abbot of Cîteaux, the principal legate, then summoned to his assistance twelve abbots of his order, elected by a chapter held in 1206, and also admitted to a participation of their labours two Spaniards, whose zeal prompted them to preach against the heretics, and one of whom became afterwards celebrated as the founder of a new order in the Catholic Church. These were Diego Acebes, Bishop of Osma, who was then on his return from Rome to his diocese, and Dominic de Guzman, a regular canon of St Augustin, and sub-prior of the cathedral of the same diocese, who had accompanied the bishop in his journey. With a staff thus reinforced, some conversions were made, and when the Spanish bishop resolved to cross the frontier, he permitted De Guzman to remain in France.

At this time the great feudatories of Provence and Narbonne were almost all engaged in war with each other; and hence when the legates sent by the Pope summoned them to prosecute obstinate heretics in their states, they represented that they could not execute the orders of his Holiness, by reason of the wars which they were obliged to maintain against their neighbours. Innocent III., informed of what was passing, issued a formal order to his legates, commanding them to terminate, by their mediation, the differences which had armed the princes and great lords of this country, and to make the latter promise upon oath, to extirpate heresy, and to exterminate heretics in their domains. Nor were the legates unfaithful to the instructions which they had received. They threatened to excommunicate those who should refuse obedience to the orders of the Holy See; to lay their principalities under interdict; to release their vassals from their oath of fidelity; and, in a word, to punish them by all the means which the church had or claimed a right to employ against rebels. The effect of this measure was decisive; and the great lords, dreading evils still greater than those of war, renounced for the time their different pretensions, and consented to sign a peace. Of these princes the most powerful was Raymond VI., Count of Toulouse. Having been several times menaced by Pierre de Castelnau, because he hesitated to execute what he had promised, and failed to reinforce the predications of the legate by proscription and confiscation, the proud noble let fall some expressions of resentment. His words were treasured up by those who had deeper wrongs to avenge, and falling in with the feeling of indignation excited by the insolent conduct of the churchman, they induced the Albigenses to assassinate the legate. The latter was beatified, and enrolled amongst the martyrs of the church, sooner perhaps than he had anticipated; but the perpetrators of the crime were destined ere long to taste its bitter fruits. Meanwhile the Pope wrote to all the counts, barons, seigneurs, and gentlemen of the provinces of Narbonne, Arles, Embrun, Aix, and Vienne in Dauphiné, urging them to unite their forces and to march against these heretics, and promising them the same indulgences as if they had been called to combat against the Saracens. In this expedition, Innocent named as his legate the Bishop of Couserans, who was to be accompanied by the Abbot of Cîteaux.

The commencement of the Inquisition in France dates from the war undertaken against the Albigenses, and their protector Raymond VI., Count of Toulouse, in 1208. The murder of Castelnau having excited the indignation of the Catholics of Narbonne, Arnauld took advantage of this feeling, to put in execution the orders which he had received from the Pope. He charged the twelve monks of his order who were associated with him, besides Dominic de Guzman, and certain other priests, to preach a crusade against the heretics; to grant indulgences to all who should take part in the war; to take especial notice of those who might refuse to engage in it; to inform themselves particularly as to the creed of such recusants; and to cause the obstinate to be placed at the disposal of Simon, Count de Montfort, who had been entrusted with the command of the crusaders. The authentic act by which these measures were ordained, has not reached our time; but its existence is proved generally by the events of that epoch, and, in particular, by a certificate of reconciliation granted by Dominic de Guzman to a heretic named Ponce Roger, in which the founder of the Dominicans declared that he acted as the delegate of the Abbé Arnauld.

It is not easy to determine the number of the unfortunate Albigenses who perished in the flames after 1208, the year in which the Inquisition commenced in France. But it is impossible not to be strongly moved with horror as well as compassion, in reading the histories of the time, which represent the destruction of several millions of persons, in the midst of the most cruel torments, as the triumph of a religion on which its divine Founder had impressed the characters of humanity and charity, benevolence and mercy. The apostles, upon one occasion, entreated their divine Master to cause fire to descend from heaven and consume the Samaritans, who were the heretics and schismatics of the Hebrew communion; but, so far from complying with their impious request, he reproached them for entertaining the very thought, and made them feel that he detested it, by treating them with a degree of severity of which there is no other example to be found in the Gospel. This lesson, however, was lost upon the men of the thirteenth century. They seem to have conceived that the history of Samaria had nothing in common with the conduct which ought to be pursued towards the heretics of that age. In 1215, Innocent III. celebrated the tenth general council, being the fourth of Lateran, in which a variety of new penalties were decreed against the heretics of Languedoc. In particular it was ordained, that those who were condemned by the bishops as impenitent heretics should be delivered to secular justice; that the goods of laymen condemned should be confiscated, and those of priests applied to the use of their churches; that the inhabitants suspected of heresy should be summoned to purge themselves in the canonical form, and, in case of refusal, excommunicated; that if they continued more than a year under the anathema, without having recourse to the pardon of the church, they should be accounted heretics, and treated as such; that all persons who favoured or received into their houses heretics, should be liable to excommunication as well as the heretics themselves,—declared infamous, and as such excluded from all public employments,—deprived of the right of electing their own magistrates,—and rendered incapable of giving evidence in a court of justice, making testamentary dispositions, or taking up any succession, if at the expiration of a year they had failed to perform their duties and satisfy the church.

Pope Innocent III. died on the 12th of July 1216, and two days thereafter was succeeded by Honorius III., who resolved to continue the work which his predecessor had commenced. The new pontiff approved of the institution founded by Dominic de Guzman, according to the rule of St Augustin, and having for its object to preach against the heretics; an institution which gave rise to the order of preaching friars, who were afterwards termed Dominicans. He wrote to Guzman, praising his zeal, and encouraging him to persevere in the enterprise in which he had engaged; he sent into the provinces of Languedoc and Provence, Cardinal Bertrand, with the title of legate, the principal object of whose mission was to prosecute with new vigour the war against the Albigenses, to sustain the zeal of the missionaries, and to ensure the reconciliation of converted, as well as the punishment of obstinate heretics; and, lastly, he issued a brief addressed to all the bishops of Christendom, strongly recommending to their favour and support the order of preaching friars.

Meanwhile St Dominic, who happened to be at Rome, had instituted an order for seculars who lived in the world, the members of which were to be bound to assist, as far as they could, those who preached against heresies, and to prosecute heretics with unrelenting rigour. This order has sometimes been designated the Third Order of Penitence, but it was more commonly denominated the Militia of Christ, because those who entered it were required to combat heretics, and to aid the inquisitors in the exercise of their ministry. They were in fact regarded as forming part of the family of the inquisition, and, for this reason, they bore the name of *Familiars.* Here, then, we have the two great elements of the Holy Office; first, the institution of St Dominic, or the order of preaching friars, called Dominicans; and, secondly, the Militia of Christ, an association which afterwards gave rise to that which was known under the name of the Congregation of St Peter Martyr; two orders which were soon confounded, and the members of which were denominated *Familiars of the Holy Office of the Inquisition.*

Nor was it long ere the tribunal, thus organized, commenced active operations against heretics. In 1224, the Inquisition had been established in Italy, under the direction of the religious Dominicans. This is proved by a constitution of Frederick II., published at Padua in February 1224, which provided that heretics condemned as such by the church, and delivered over to the secular arm, should be punished in a manner proportioned to their crime; that whosoever, through fear of punishment, might be brought back to the unity of the faith, should be subjected to a canonical penance and shut up in prison for life; that the inquisitors established by the pope, or Catholics zealous for the purity of the faith, might require judges, in any part of the empire, to cause heretics to be seized, and detained as prisoners until, after being formally excommunicated by the church, they were judged and punished with death; that all who supported or protected heretics should undergo the same punishment; that heretics who had returned into the bosom of the church should be obliged to pursue those persons charged with heresy, discover, and bring them before the Inquisition; that he who, having made abjuration *in articulo mortis*, should relapse into heresy after recovering his health, should equally suffer a capital punishment; and that treason against God was a much greater crime than treason against man. This constitution contains other provisions equally severe, and concludes by declaring that all those who should concur with the new religious order in delivering the empire from the contagion of heresy, would serve God and render themselves useful to the state. It appears, however, that the efforts of the Inquisition in Narbonne, were not attended with the success which the Pope had expected from them, probably because the events of the war were not always favourable to the crusaders.

But it was reserved for Gregory IX., who ascended the pontifical throne in 1227, to fix the establishment of the Inquisition in the form of a tribunal, and at the same time to give it constitutions. With this view he convened a council at Toulouse, where new measures of severity were adopted against the heretics; he also issued a bull excommunicating them, and further, enjoining that the impenitent should be delivered over to the secular arm, and that all their supporters and adherents should be declared infamous. He next transmitted a brief to Esparrago, archbishop of Toledo, exhorting him to combat heresy; and at the same time addressed to the prior of the Dominicans of Lombardy a commission, confiding to that religious order the execution of his bull against heretics. Councils were also held at Melun, and at Beziers, where new regulations were adopted for preserving the purity of the faith, by multiplying the severities against those by whom it was denied.

But whilst this was passing in France, the heresy of the Albigenses penetrated even into the capital of the Catholic world. The extreme means of repression hitherto employed against these schismatics had totally failed either in lessening their ardour, or in abating their enthusiasm. Several thousands of their number had perished at the stake in France and Italy; yet, so far from being discouraged, they had, in defiance of the power of the Pope, carried their doctrines into his very capital, and, by this conduct, proved how much they disregarded the anathemas of the church, and even the horrible torments with which Gregory had menaced them. Nor is it improbable that the pontiff would have abandoned the system of repression which he had adopted, if the opinions which originated in the fourth century, when Constantine embraced Christianity, had not from age to age acquired a new degree of force; namely, that sufficient reasons might be discovered in the Gospel for punishing heretics with death. Unhappily, however, men's minds, subjugated by prejudice, and inflamed by bigotry, were rendered incapable of considering objects in their true light. Hence, so far from changing his system, or taking as his guide that spirit of meekness and benevolence which had distinguished the first three centuries of Christianity, Gregory fulminated against the heretics a bull in which he excommunicated all those belonging to certain classes that are therein named; ordained that the persons condemned should be delivered over to the secular power to receive the punishment due to their crime; regulated the mode of procedure to be adopted against persons accused of heresy; intercommuned, declared infamous, and deprived of their civil rights, those inhabitants who should receive into their houses, protect, or defend reputed heretics; and provided that if any one desired to recant and renounce his errors, he should undergo such penance as might be prescribed, and thereafter be imprisoned for life. This bull, which contained many other penalties and disabilities, was enforced with the utmost rigour; whilst the senator Annibal, and other members of the government of Rome, in order to second the Pope in the execution of the measures which he had ordained, passed different municipal laws, having for their object the detection and punishment of heretics, and being in spirit and character nearly the same with those which had been promulgated by Frederick II.

Nor were these regulations confined in their operation to Rome. They were transmitted, along with those which Gregory himself had decreed, to the Archbishop of Milan, in order that he might cause them to be rigorously executed in his own diocese, in those of his suffragans, and in some other parts of Cisalpine Gaul, where heresy had already made alarming progress. Frederick II. also renewed the constitutions which he had published against heretics in 1224, particularly the law against blasphemers, which condemned all heretics indiscriminately to undergo the punishment of burning, or of having the tongue cut out, if the bishops thought proper to shew them mercy, in order that in future it might be impossible for them to blaspheme the holy name of God.

Such is the general form which the Inquisition had assumed in France and Italy, when Gregory IX. introduced it into Spain. This event took place about the middle of the thirteenth century. Spain was then divided into four Christian kingdoms, viz. Castille, Navarre, Aragon, and Portugal, besides the Mahommedan States; but, with relation to the Inquisition, that country was, in 1301, divided into two provinces, viz. those of Castille and Aragon. To the Dominicans, who had hitherto acquitted themselves with success in the ministry of persecution, Gregory confided the execution of the bull by which the Inquisition was established in Spain; and, at a subsequent period, the provincial of this order had conferred upon him the right of nominating the local inquisitors, with the title and rank of provincial of Spain. Nor was it long ere this formidable institution, having for its object to extirpate heresy, and to preserve the purity of the Catholic faith, came into active operation. For the details of its proceedings, however, we must refer the reader to the work of Llorente,[1] which, with all its faults of style and arrangement, contains a vast body of interesting and authentic information on this subject. We shall only remark here, that never did plant find a more congenial soil. In France and in Italy it had required strenuous and persevering efforts to organize and establish this terrible tribunal; in Spain, however, it took root at once, and in time attained a magnitude which, from a variety of causes, it never reached in any other country. During the fourteenth century its progress was steady, whilst its vigour and energy were continually on the increase. Its jurisdiction was enlarged, and its ramifications multiplied; *autos-da-fe* were celebrated in various places; and many perished in the flames, or were condemned to suffer punishments of greater or less severity, for asserting the unalienable rights of conscience.

But it was not until towards the close of the fifteenth century, when Isabella, wife of Ferdinand of Aragon, had ascended the throne of Castille, and when the different kingdoms of Spain were united under these sovereigns, that the Inquisition became general in that country, and assumed that form which it retained until the period of its dissolution in 1808. The execution of the bull of Sixtus IV., which authorized Ferdinand and Isabella to establish the Inquisition in their states, was indeed for a time suspended; but this suspension must have been of short duration, for in 1480 and 1481 we find it in full activity. Severe measures were adopted against the Jews, who were accused of the most absurd and ridiculous crimes, and in consequence the new Christians, as they were called, emigrated in great numbers. The flames of persecution raged at Seville, where, in 1481, twenty-six persons perished at the stake; and already no less than two hundred and ninety-eight victims had shared a similar fate. From this period, indeed, may be dated the establishment of the modern Inquisition, that is, of the Inquisition such as it existed even until our own time. This was effected by the creation of a grand inquisitor-general; the appointment of a royal council of the Inquisition, afterwards denominated the Council of the Supreme; the institution of subaltern tribunals in all parts of the kingdom; and, lastly, the enactment of organic laws, having for their object to give stability to the tribunal, as well as uniformity to its procedure, and efficacy to its exertions in the repression of heresy. By this organization there was created in Spain a jurisdiction in matters of religion, which, under the able but merciless direction of such men as Torquemada, Valdez, and their immediate successors, became the most effective and vigorous engine of persecution which had ever before been known in any age or country. Its character will be best understood by stating the substance of the organic or fundamental laws of the modern Inquisition, which, under the name of *Instructions*, were published at Seville on the 29th of October 1484.

The first of these regulated the manner in which the institution of the tribunal should be announced in those countries or places where it might be judged necessary to establish it. The second ordained the publication, in the church of the place, of an edict accompanied with the *censures* provided against those who, having committed the crime of heresy or apostasy, should not voluntarily denounce themselves before the expiration of the term of grace which had been granted them, and also against those who should obstruct or resist the execution of the measures ordained by the Holy Office. By the third, a delay of thirty days was allowed to heretics to declare themselves, and thereby to prevent the confiscation of their goods, without prejudice, however, to the pecuniary fines to which they might afterwards be condemned. By the fourth, it was provided that the voluntary confessions of those who declared themselves should be made in writing in the presence of the inquisitors and a registrar, so that the self-accused might be required to answer all the questions which might be addressed to them by the inquisitors on the subject of their confession, and also respecting their accomplices, and those whom they knew or suspected to be guilty of apostasy. The fifth prohibited giving secret absolution to any one who had made a voluntary confession, excepting in the single case where no one had had knowledge of his crime, and where there was nothing to apprehend from its publicity. By the sixth article it was provided that part of the penance enjoined on him who had been reconciled should consist in his being deprived of the exercise of every honourable employment, and of the use of gold, silver, pearls, silk, and fine linen. The seventh imposed pecuniary fines upon those who had made a voluntary confession. The eighth provided that the voluntary penitent who might present himself with his confession, after the expiration of the term of grace, should not be exempted from the penalty of confiscation of goods, which he would otherwise have incurred. In the ninth article, it was enacted, that if persons under the age of twenty presented themselves to make confession, after the expiration of the term of grace, and if it were proved that they had been led into error by their parents, it would be sufficient to impose on them a slight penance. The tenth imposed on inquisitors the obligation of declaring, in the act of reconciliation, the time in which the reconciled had fallen into heresy, in order to ascertain what portion of his goods belonged to the fisc. The eleventh article bore, that if a heretic detained in the secret prisons of the Holy Office, were touched with due repentance, and demanded absolution, it might be granted him, by imposing as a penance the pain of perpetual imprisonment. By the twelfth, it was provided, that if the inquisitors considered the confession of the penitent to have been simulated, in the case indicated in the preceding article, they should refuse absolution, declare him a false penitent, and condemn him as such to be *relaxed*, that is, delivered over to the secular arm. The thirteenth ordained that if a man, absolved after free confession, boasted of having concealed several crimes, or if it appeared, from information afterwards obtained, that he had committed more than he confessed, he should be arrested, and judged as a false penitent. The fourteenth provided, that if the accused, when convict-

[1] *Histoire Critique de l'Inquisition d'Espagne*, Paris, 1818, 4 vols. 8vo. Llorente had been an inquisitor himself (at Calatayud) and was probably on that account selected to prepare a digest of the materials for a history of the Inquisition, furnished by the archives of the Holy Office.

ed, persisted in denying the charge, even after the publication of the evidence, he should be condemned as impenitent. By the fifteenth, if there were only a *semi-plena probatio* against the accused, who denied the crime charged against him, he might be subjected to the question; in which case, if he confessed himself guilty under the torture, and thereafter confirmed his confession, he was punished as one regularly convicted; but if he retracted, he was to undergo, a second time, the same probation, or to be condemned to an extraordinary punishment. The sixteenth prohibited communicating to the accused an entire copy of the declarations of the witnesses. They were only to be informed generally what had been deposed, without being made aware of any circumstances which might enable them to discover who had given evidence against them. The seventeenth article enjoined inquisitors themselves to interrogate the witnesses, in every case where it was possible for them to do so. The eighteenth provided that two inquisitors should be present when the person arraigned was put to the question; but if otherwise occupied, they might appoint a commissary to receive the declarations of the sufferer. By the nineteenth article, if the accused did not appear, after having been cited according to the prescribed forms, he might be condemned as a convicted heretic. The twentieth bore, that if it were proved by the books, or by the conduct whilst in life of a person deceased, that he had been a heretic, he might be judged and condemned as such, his corpse disinterred, and the whole of his property confiscated to the state, at the expense of his natural heirs. By the twenty-first article, the inquisitors were ordered to extend their jurisdiction over the vassals of the great lords; and if the latter refused to recognise it, to apply to them censures and other penalties. The twenty-second provided that if the person condemned to be *relaxed* to the ordinary tribunal left children minors, a small portion of the confiscated property of their father should be granted them by the government, in name of alms, and the inquisitors should be obliged to confide to proper persons the care of their education and Christian instruction. By the twenty-third, if a heretic reconciled during the term of grace, without having incurred the penalty of confiscation, should have acquired property from a person who would have been condemned to that penalty, such property was not to be included in or protected by the law of pardon. The twenty-fourth rendered it obligatory to restore to liberty the Christian slaves of the reconciled, when confiscation had not taken place, provided the king had granted pardon only on that condition. The twenty-fifth article prohibited the inquisitors, and other persons attached to the tribunal, from receiving presents, under pain of incurring the greater excommunication, being deprived of all their employments, condemned to make restitution, and amerced in twice the value of the articles received. The twenty-sixth recommended to the officers of the Inquisition to live in peace with one another, without affectation of superiority even on the part of him who might be invested with the powers of the ordinary of the diocese; and, in case any difference should arise, it was reserved for the inquisitor-general to settle it quietly (*sans éclat*). By the twenty-seventh, inquisitors were expressly enjoined to watch carefully over their subordinates, in order that the latter might be exact in discharging their duties. Lastly, the twenty-eighth article committed to the prudence of the inquisitors the examination and discussion of all points which might not have been provided for in the foregoing constitutions.

Such is the substance of the Code of the Inquisition, as originally promulgated, perhaps the most extraordinary digest ever formed for consolidating a system of religious tyranny. From this abstract, indeed, it must be evident, whether we examine the twenty-eight articles in detail, or consider them as a whole, that the judgments and sentences pronounced would depend upon the manner in which the charge was prepared, and the particular views and feelings entertained by the judges, who were to decide as to the heresy or orthodoxy of the accused, according to inductions, analogies, or consequences, deduced from facts or isolated observations, reported with more or less of exaggeration and infidelity.[1] The code in question was, however, several times augmented, even in the early days of the Inquisition. In particular, there were added to it the instructions which had been prepared at Seville in the beginning of 1484, those of Valladolid in 1488, those of Toledo and Avila in 1498, and, lastly, those of Valladolid in 1561. But with all these modifications the forms of procedure underwent little or no change; nor was the arbitrary character which distinguished this cruel and odious jurisprudence in any degree mitigated. It was scarcely possible for the accused, however innocent, to establish an effectual defence. Placed between the alternative of either recognising his innocence, or suspecting him of guilt, the judges constantly allowed themselves to adopt the latter course, which at once superseded the necessity of proof, and left the accused entirely at their mercy.

The additional acts of the inquisitor-general Torquemada also fall under the description which has already been given. They were eleven in number, and principally intended to regulate details. They provided that in every subaltern tribunal there should be two inquisitor-jurisconsults, a fiscal, an alguazil, registrars, and other officers if required; that every functionary who received presents either from the accused, or their families, should be immediately dismissed; that the Inquisition should maintain at Rome an able jurisconsult, with the title of agent; that contracts signed before the year 1479 by persons whose goods happened to be seized after that period, should be valid; that proprietors who might have afforded to fugitives an asylum on their estates, should be held as having placed their whole property at the disposal of the government; that the notaries of the Inquisition should keep accounts of the effects of persons condemned; that the receivers of the Holy Office might sell that property, the administration of which they found troublesome, and collect the rents of such as was immoveable; that each receiver should attend to the interests of the tribunal to which he was more immediately attached; that the goods of a person condemned could not be sequestrated without an order of the Inquisition; that the inquisitor and other officers should be paid their salaries quarterly by the receiver; and that, in regard to circumstances unprovided for in the new constitutions, the inquisitors should have a discretionary power to act as they judged best, but that, in matters of great importance, they should have recourse to the government for instructions.

The crimes of which the Inquisition took cognisance were heresy in all its different forms, apostasy, Judaism, Mahommedanism, sorcery, offences against nature, and polygamy; and the punishments consequent on conviction varied according to the presumed degree of delinquency, from temporary confinement and severe penance to the *san benito*[2] and the *auto-da-fe*. This tribunal was not esta-

[1] "Que devait-on attendre de tels hommes, devenus les arbitres de la vie et de la mort de leurs semblables, en les voyant complettement aveuglés par leurs préventions contre des accusés sans défense? L'homme simple devait succomber; l'hypocrite seul triompha."—(Llorente, *Hist. Crit. de l'Inquisit. d'Espagne*, i. 184.)

[2] *San benito* is a corruption of *saco bendito*. Its true name in Spanish was *zamarra;* but *saco bendito*, corrupted into *san benito*, became the vulgar name, because, since the time of the Hebrews, a *sack* was the habit of penitence.

blished without great opposition. The first inquisitor of Aragon was openly assassinated, and all the provinces of that kingdom offered the most strenuous resistance to a jurisdiction which trenched so much on their ancient rights and privileges. But their opposition proved unavailing, as did also an attempt made by the Cortes of Castille and Aragon to reform the Holy Office after it had been established. The Inquisition triumphed over all its adversaries, and soon became so formidable, that parents delivered up their children, husbands their wives, and masters their servants, without a murmur. Terror, in fact, constituted the great element of its power; nor was this feeling diminished in force by the suddenness with which it pounced on its victims, and the impenetrable secrecy in which all its proceedings were involved. Its stroke was like that of fate. No man knew when it might descend on his own head; every one felt that resistance was vain, and escape impossible. Imagination lent its aid to exaggerate the fearful reality; terror froze all hearts; even kings and princes trembled before it. Nor can it be denied that, in its high and palmy days, its proceedings were marked by a bold and fearless impartiality. It scrupled not to arrest and proceed against Don Carlos of Austria, prince of the Asturias, whom death alone placed beyond the reach of its sentence. It instituted processes against Charles V., Philip II., the Duke of Alba, and other illustrious personages, the first of whom was accused of favouring Lutheranism, and the others were charged with want of zeal in the prosecution and extermination of heretics. Nor was it in any respect more lenient to the clergy than to the laity. Bartolomeo Carranza, archbishop of Toledo, a prelate of eminent learning, piety, and moderation, was accused of entertaining and countenancing certain opinions declared to be heretical, imprisoned for several years, and, after enduring the greatest sufferings, died before his process was brought to a close, though it ended in a sentence of absolution. With regard to the inferior clergy, a charge of heresy, or even the suspicion of having shewn kindness to heretics, was almost equivalent to a capital condemnation. Neither rank, nor age, nor sex, afforded any defence against its watchful vigilance and its pitiless severity. It was instituted to preserve the uniformity of the faith, and, in Spain at least, it completely succeeded.[1]

Nor can it be doubted that the procedure of the Inquisition was eminently calculated to accomplish the objects for which it had been originally instituted. This consisted of several parts; namely, the denunciation, the inquest, the censure by qualificators, secret imprisonment, the primary audiences, the charges, torture, the requisitory, the defence, the proofs, the publication of the proofs, the definitive censure by qualificators, and the sentence.

The procedure of the Holy Office commenced by denunciation, or something held equivalent thereto, such as a discovery incidentally resulting from a deposition made before the tribunal in another affair; and this, when signed, assumed the form of a declaration, in which the delator, after having sworn to tell the truth, designated by their names, or in some other manner, the persons whom he believed or presumed to be able to give evidence against the denounced. Then followed the inquest, or examination of the persons named and designed in the declaration as cognisant of the facts and circumstances therein set forth, and who were made to promise upon oath that they would never reveal the interrogatories which they were to be called upon to answer. Next came the censure by the qualificators. When the tribunal had examined the preliminary *instruction*, and discovered therein sufficient grounds for further procedure; and when the registers of the other tribunals of the province had been examined, to ascertain if there existed in these any charges against the denounced; the whole was submitted by the inquisitors to certain theologians, called *qualificators of the Holy Office*, who indicated or *qualified* in writing the propositions meriting theological censure, as heretical, savouring of heresy, or calculated to lead to heresy: And in case the denounced was only suspected of this crime, they decided whether the suspicion was *light*, *grave*, or *violent*. As soon as the qualification here described had been made, the procurator-fiscal demanded that the denounced should be transferred to the secret prisons of the Holy Office. The tribunal had three sorts of prisons; public, intermediary, and secret. The first were those in which the Holy Office caused to be confined persons who, without being guilty of any crime against the faith, were accused of some delict, the punishment of which belonged of right to the Inquisition. The second were destined for such servants or ministers of the Holy Office as had committed some crime or some fault in the exercise of their functions, without, however, incurring the suspicion of heresy. The third or secret prisons were those in which heretics, or persons suspected of being so, were confined, and where the prisoners could only communicate with the judges, in the cases provided and with the precautions enjoined by the constitutions.[2]

In the three days which followed the imprisonment of the suspected, they gave him three audiences of *monition* or advice, to engage him to speak the truth and the whole truth, without concealing any thing which he had himself done or said, or which he could impute to others contrary to the faith. He was also told, that if he conformed faithfully to what had been prescribed to him in this particular, mercy would be shewn him, but that, in the contrary case, he would be treated with all the rigour of law. After the formality of the three audiences of monition had been gone through, the procurator-fiscal prepared the indictment against the prisoner, in conformity with the heads of accusation indicated or *qualified* in the *instruction*; and although there existed only a *semi-plena probatio*, he charged the facts deposed to as if they had been fully proved, and what was worse, he did not limit the articles or counts of his indictment to the number of facts declared, and dispensed with applying to each head of accusation the proper character or notion which distinguished it. The next part of the procedure was the most horrible, namely, the application of the torture. Although the prisoner, in the three audiences of monition, might have confessed as much as, or even more, than the witnesses had deposed to, the fiscal terminated his requisitory or accusation, by demanding that the accused should be subjected to the question, on the alleged ground

[1] See Llorente, *Hist. Critiq. de l'Inq. d'Espagne*, tom. iv., and M'Crie's *History of the Reformation in Spain.*

[2] " Il serait difficile de rien concevoir de plus affreux que ces réduits," says Llorente; " non qu'ils soient à présent tels qu'on les a décrits, c'est-à-dire profonds, humides, sales et mal-sains: à ces traits il est plus facile de reconnaître les rapports inexacts et exagérés des victimes de l'Inquisition que le témoignage de la vérité. Je ne parlerai de ce qu'ils ont été autrefois, mais il est certain qu'aujourd'hui ces lieux sont de bonnes chambres voûtées, bien eclairées, sans humidité, et où il est permis de faire un peu d'exercice. Mais ce qui les rend un séjour vraiment redoutable c'est qu'on n'y entre sans être à l'instant flétri dans l'opinion publique; infamie à laquelle aucune autre, soit civile, soit ecclésiastique, n'expose les prisonniers; c'est qu'on y tombe dans une tristesse inexprimable, compagne inévitable d'une solitude profonde et continuelle; c'est qu'on n'y connait jamais l'état de la procédure dont on est l'objet, et qu'on ne peut y jouir de la consolation de voir et entretenir son défenseur; enfin, c'est parcequ' on y est plongé pendant l'hiver dans des ténèbres de quinze heures par jour, car il n'est point permis au prisonnier d'avoir de la lumière après quatre heures du soir ni avant sept heures du matin; intervalle assez long pour qu'une hypochondrie mortelle s'empare du prisonnier, au milieu du froid, dont il est saisi dans un séjour où le feu n'a jamais pénétré." (*Hist. Crit. de l'Inquisit. d'Espagne*, i. 300.)

of culpable concealment and denial of the truth. It is certain that for a long period the torture had not been applied by the inquisitors, either in Spain or in any other country, the mitigating and humanizing influence of time and improvement having virtually abolished this barbarity; but the form of procedure still remained unchanged. The *requisitory* or accusation of the fiscal was never communicated in writing to the accused, to enable him to prepare his defence. He was conducted into the hall of audience, where, in presence of the inquisitors and the fiscal, a secretary read over the charges one after another, stopping at each article, and calling upon the accused to answer at the instant, whether it was conformable to the truth or otherwise; thus laying a snare for the unhappy person who was about to be put on his trial. After the accusation had been read, the inquisitors asked the accused if he wished to be defended. If he answered in the affirmative, they ordered a copy to be taken of the accusation and answers, and, from the list of titularies of the Holy Office, appointed him an advocate. No prisoner was permitted to choose his own counsel, although there existed no law of the Holy Office which denied him this just and natural right. To the proof, and the publication of the proof, as it was called, both gross mockeries of justice, succeeded the definitive censure by the qualificators, or theologians of the Holy Office, to whom was remitted the original of the judgment they had pronounced on the summary instruction, together with an extract of the answers made by the accused in his last examination, and who were required to qualify for the second time the propositions upon which the accusation was founded, to consider the explanation given by the prisoner, and to decide whether he had, by his answers, elided in whole or in part the suspicion of heresy with which he was charged, or whether, on the contrary, he had not fortified the suspicion of his guilt. The importance of this censure must be evident, since on it depended the definitive sentence. Yet, says Llorente, "les *qualificateurs* se donnent à peine le temps d'écouter une lecture rapide de ce qui s'est passé; ils se hâtent d'établir leur opinion, et c'est là le dernier acte important de la procédure," all the rest being a simple formality. Lastly, came the sentence, which, as may easily be anticipated from the nature of the procedure, was generally condemnatory of the prisoner. In fact, before the reign of Philip III., sentences of absolution were so rare in the Holy Office, that in one or even two thousand judgments we scarcely find an instance where the prisoner was fully acquitted, because the slightest doubt as to the complete innocence of the accused led the qualificators to declare him suspected *de levi*, and this was sufficient to induce the inquisitors to condemn him to suffer pains more or less grave, according to circumstances, and to make a formal abjuration of all kinds of heresy, particularly of that of which he had incurred the suspicion.

> Devant l'Inquisition, quand on vient à jubé
> Si l'on ne sort rôti, l'on sort au moins flambé.

The reading of the judgment formed the finale of the procedure which we have been endeavouring to describe; and the execution of it always commenced in the same *auto-da-fe* where it was read and signified.
